Cathodic inhibitors are usually substances that slow the rate of the oxygen reduction reaction on aluminum alloy surfaces. By slowing down oxygen reduction, the companion aluminum oxidation reaction must also slow down. This results in an overall decrease in the corrosion cell kinetics, as well as a decrease in the free corrosion potential. For the best inhibitors, the decrease in the corrosion potential is usually to a value well below the alloy's pitting or repassivation potential. Cathodic inhibitors have the advantage of being able to improve corrosion resistance at very low concentrations. For example, chromate added at micromolar concentrations to an aerated dilute chloride solution is enough to significantly reduce the rate of oxygen reduction leading to significant corrosion protection.

Soluble corrosion inhibitors are usually ions in solution. Important inorganic anions that inhibit aluminum corrosion include chromate, phosphate, permanganate, nitrate, vanadate, molybdate, tungstate and silicate. Cations of strontium, cerium and the lanthanides as well as zinc are inorganic cationic inhibitors. Organic substances that are inhibitors of aluminum corrosion include phosphonates, sulfonates, benzoates, thiols, azoles, amines, fatty acids and natural compounds such as tannins. Among these, special attention must be given to chromates. Chromate is an exceptionally powerful inhibitor of oxygen reduction and an excellent inhibitor of aluminum corrosion. Chromates are used across all industries as aluminum corrosion inhibitors. However, their use is becoming increasingly restricted over concerns for work-place safety and environmental pollution because chromates are human carcinogens.

Inhibitors can be incorporated into coating systems in a variety of ways. Sparingly soluble inorganic compounds and ion exchange materials are used as corrosion inhibiting pigments in coating formulations. Inhibitor ions can be attached to reactive sites on coating resin polymers or directly applied to aluminum surfaces using an evaporable solvent.

### **3.08.6.2 Conversion Coatings**

Conversion coatings, which are frequently referred to as pretreatments or pretreatment coatings, are applied to aluminum and aluminum alloys to improve corrosion resistance or to improve adhesion of subsequently applied organic coatings and adhesives.

From a technological and processing perspective, conversion or pretreatment coating of aluminum is analogous in some ways to phosphating of steel and passivation of stainless steels. The conversion coating process involves contacting the surface to be coated with an aqueous solution containing surface activators and coating-forming ingredients. Contact times in commercial processes range from seconds on a continuous coil processing line to minutes for certain aerospace applications, and solution contact with the surface can be applied by immersion, spraying or rolling. Coating solutions are operated at or slightly above room temperature, and bath stability is maintained under careful control using guidelines from the pretreatment system supplier. Commercial conversion coating processes are well supported by suppliers, and methods for maintaining coating baths and ensuring coating quality are almost always provided.

Conversion coatings are not as protective as anodized coatings, and in most cases, conversion-coated surfaces are subsequently primed or painted. Conversion coatings are used for stand-alone corrosion protection when mild to moderate, occasionally condensing, atmospheric exposure conditions are expected, or for temporary corrosion protection.

Pretreatment of aluminum has relied extensively on chromate-based systems. There are two general classes of chromate conversion processes: the activated acidic formulations such as the chromium chromate processes that use a sodium fluoride–chromic acid chemistry, and alkaline oxide processes based on a sodium chromate–sodium hydroxide or carbonate chemistry. Activated acid processes have been the dominant process across many industry sectors for over 50 years. In finished form, conversion coatings produced are a light to deep yellow, continuous, and conformal across the surface with thicknesses ranging from 0.1 to 1.5  $\mu\text{m}$  depending on coating bath contact time. Freshly formed coatings are gelatinous and require at least a day to harden before handling. Such coatings can prevent pitting for several thousand hours of continuous salt spray exposure. Alkaline oxide coatings fell out of common use with the emergence of activated acidic formulations. Alkaline oxide coatings are thicker, less uniform and occasionally dusty. Coating baths produce much sludge and are difficult to maintain.

Chromate conversion coatings are noted for their ability to self-heal. Self-healing refers to the ability of the coating to resist corrosion from scribes or defects in the coating. This phenomenon is attributed to the release of labile hexavalent chromium in the coating

into an aggressive solution contacting the surface. Chromate ions are released by the coating, and can be transported to the site of damage to participate in repair of the film by reduction of the chromate to a chromic species that bond with the aluminum substrate and the existing conversion coating.

Chromate is a human carcinogen, and chromate-based coatings are banned in many countries. In response to this ban, trivalent chromium conversion coatings have been developed. These coatings provide useful levels of corrosion protection, but are not as protective as chromate conversion coatings. They are also observed to perform better on certain alloys than others.

There has been a major worldwide initiative to develop chrome-free pretreatment systems for aluminum alloys. Successful chrome-free pretreatment of aluminum alloys depends on a number of critical factors ranging from alloy and process route selection through to appropriate surface cleaning and how corrosion or durability testing is carried out to compare chrome-free and chrome-based systems.

Recent results have shown that the severity of corrosion of coil-coated aluminum architectural sheet is directly related to the manganese content of the alloy. This means that alloys such as AA3003, AA3103, AA3004, AA3104 and AA3005 are all potentially more susceptible to corrosion than alloys with a lower manganese level, such as AA3105, or AA5050, AA5251, AA5754, etc. It is quite difficult to make the low-manganese AA3xxx or AA5xxx alloys susceptible to corrosion under paint films.

Generally, the corrosion susceptibility of painted aluminum is due to an active surface layer.<sup>122–128</sup> This arises from the high level of surface shear induced during rolling, which transforms the near-surface microstructure. Deformed surfaces are characterized by an ultrafine grain size that can be stabilized by magnesium oxide pinning in magnesium-containing alloys.<sup>129</sup> A typical deformed surface layer on an AA3104 alloy after hot rolling is shown in **Figure 12**.

However, it is not the fine grain size that is responsible for the corrosion susceptibility of the surface layer. This susceptibility is promoted by the preferential precipitation of manganese-rich dispersoids during annealing treatments. Susceptibility is directly related to density of precipitated dispersoids, which, in turn, depends on the manganese solid solution level and the temperature and time of annealing. This is why manganese has such a strong influence on corrosion susceptibility.<sup>130–132</sup>

**Figure 12** TEM image of an ultramicroformed section of a hot-rolled AA3104 alloy after breakdown rolling showing the ultrafine grains pinned by magnesium oxide particles. Courtesy of Yanwen Liu.

Deformed surface layers on aluminum alloys are produced most readily by hot rolling, and generally the layer thickness of sheets and plates after hot rolling is of the order of a micrometer. The deformed layer thickness is progressively reduced by cold rolling, so alloys that have been extensively cold rolled have thinner deformed layers that can more readily be removed by conventional etch-cleaning operations. This means that resistance to corrosion can be improved by increasing the transfer gauge thickness so that after cold rolling the amount of surface to be removed at final gauge is 0.2  $\mu\text{m}$  or less.

Another route to reduce susceptibility is to homogenize rolling blocks before hot rolling to precipitate out the manganese from solid solution. This is equivalent to using a lower manganese-containing alloy. A further possibility is to eliminate hot rolling by using either roll-cast or thin belt-cast production routes. This is particularly effective when used in combination with appropriate alloy selection.

Cleaning is the most critical process step to provide alloy surfaces that can be successfully pretreated with a chrome-free pretreatment. Basically, the corrosion active surface layer must be removed using either an acidic or alkaline treatment. The amount of metal to be removed depends directly on the layer thickness, and this means that cleaning is facilitated where there has been significant cold rolling to reduce layer thickness. In low-magnesium alloys, the ultrafine grains are usually annealed out, but there is still a preferential precipitation of dispersoids compared to the bulk microstructure. The entire corrosion sensitive layer must be removed. For most AA5xxx alloys, the only requirement is to remove magnesium oxide from the surface, as this can reduce adhesion particularly for bonding applications. This means that cleaning of AA5xxx alloys is much more straightforward than cleaning AA3xxx alloys, particularly those with high manganese content.

Aluminum alloys generally become immune to underfilm corrosion following effective cleaning to remove any corrosion-susceptible layers. However, it is very important to avoid accumulation of copper on the alloy surface during the cleaning operation and/or to ensure that any copper enrichment is removed by a suitable desmutting treatment. Copper is readily enriched on the surface of aluminum alloys in both acid and alkaline etching solutions. Generally, it is important that surfaces are not overcleaned and that the cleaning operation is calibrated such that the end of cleaning coincides with active layer removal. Copper enrichment during cleaning can be measured on alloys where the nominal copper level in the alloy is less than 0.1%.

The principal function of pretreatment or conversion treatment after cleaning of architectural and automotive sheet alloys is to provide good adhesion. This can be achieved by using a treatment to enhance the natural oxide layer, such as anodizing or hydrothermal treatment in water or steam. Anodizing pretreatments have been used very effectively for many years, although they are not in widespread use as coil-line treatments. Coil-line treatments are based on fast anodizing in either sulfuric acid or phosphoric acid. These types of pretreatment have the advantages of speed, control and uniformity compared to most chemical conversion treatments. They are much underutilized as chrome-free pretreatments for aluminum alloys.

Fluorotitanic- and fluorozirconic-acid-based pretreatments are in widespread use as chrome-free alternatives. Such pretreatments are effective but are more difficult to monitor in production compared to traditional chrome-based systems. This is particularly an issue where polymeric additions are made to the formulation to improve performance. For such systems, good adhesion is achieved through good surface coverage of a uniform film of either zirconium and/or titanium oxide. However, adhesion is severely compromised if the film is too thick, and this can lead to coating failure in service that is unrelated to corrosion sensitivity.

Pretreatment systems based on the use of adhesion promoters such as silanes, phosphonates and polyacrylic acids have been extensively researched. These pretreatments can be very effective especially when applied as monolayers rather than thick films. They are probably most useful when used in combination with a thin anodizing treatment or similar treatment to increase barrier film thickness and to develop a micro-surface roughness to enhance adhesion.

There is very little systematic information on the field performance of painted aluminum products. Most useful information has come from the carefully monitored exposure of sets of test panels on exposure sites. The results of these studies correlate extremely well with filiform corrosion tests and with certain cyclic corrosion tests that are not overaccelerated by acidification or the use of additions of copper salts. There is generally poor correlation with the results of acidified salt spray tests either in terms of performance ranking or in the observed mode of corrosion. It is inappropriate to use corrosion tests designed for steel substrates for aluminum, as the conditions that promote corrosion are quite different. Corrosion of painted aluminum requires the presence of chloride and a high humidity. Corrosion of aluminum under conditions of total immersion or at humidity levels of more than 95% does not show the filamental corrosion mode that is seen on exposure sites or in service.<sup>133</sup>

Corrosion on painted panels occurs most readily on marine sites when panels are exposed vertically, facing north, and the panel is protected by an overhang so that accumulated chloride is not removed by rain. Such conditions are not reproduced in most cabinet-based corrosion tests.

Although the surface of wrought aluminum products can be made corrosion resistant by cleaning to remove active surface layers, it is important that such surfaces are not damaged by subsequent high shear processes such as grinding or machining operations. This is particularly important for aluminum automotive alloys, such as AA6111 and AA6016, which are used in external closure panel applications. Mechanical grinding during processes such as rectification can readily produce an ultrafine-grain-sized surface layer as shown in [Figure 13](#). This layer is not removed during cleaning and phosphating as part of the body-in-white finishing operation. The layer can become more corrosion-active than the underlying bulk metal following paint baking. This is due to preferential precipitation of the aging precipitate in the surface layers compared to the bulk microstructure.

The situation of aluminum external closure panels is similar to using galvanized steel, in that rectification must be minimized in the areas that are susceptible to stone chip damage. For galvanized steel, surface grinding removes the protective zinc layer, whereas for aluminum, a corrosion active layer is created by the grinding and finishing operation. However, corrosion in service can occur only if the paint film is damaged to expose the bare metal.

**Figure 13** Scanning electron micrographs of the surface of an AA6016 alloy after rectification by grinding. The higher magnification image shows the ultrafine grain size of the deformed layer. Courtesy of George Thompson.

Although as-cast surfaces have not been found to be susceptible to filiform corrosion, it is possible to develop active layers on castings by grinding or machining and subsequent thermal treatment. This is probably the main influence on the corrosion of cast aluminum wheels. The surface of extruded aluminum has been studied extensively, although ultrafine grain microstructures have not been reported. However, transformed surface microstructures, particularly those with coarse grain structures, have been well documented. Resistance to filiform corrosion is also significantly improved by deep surface etching. Cutting, grinding and machining operations, following cleaning and pretreatment either before or especially after painting, are probably highly significant in promoting corrosion in service.

Secondary metal generally contains higher levels of impurities compared to primary metal. This can lead to higher levels of elements such as iron, silicon and copper and also contamination by elements such as lead, bismuth, zinc and tin. Aluminum alloys made from secondary metal can be highly resistant to corrosion using chrome-free pretreatments, provided that alloy compositions are optimized. In addition, continuous casting production routes should be chosen to minimize active layer development by eliminating hot rolling. Effective cleaning is critical, and surface enrichment of elements such as copper, lead, bismuth, zinc and tin must be avoided or such enriched layers must be removed. After such cleaning, continuously cast alloys made from secondary metal can be shown to be highly resistant to corrosion using simple chrome-free pretreatments that promote good adhesion.

### 3.08.6.3 Anodizing

Aluminum and aluminum alloys can be anodized to enhance corrosion protection and improve adhesion of subsequently applied organic coatings, and improve a range of other surface properties. For this reason, it is a very widely used process. Anodized coatings are formed electrochemically in an aqueous solution that results in an aluminum oxide surface film (see [Figure 14](#)). Anodized coatings on aluminum alloys are on the order of 2–50 µm in thickness. Aluminum anodization is usually carried out in an acidic bath that contains ingredients which promote formation of an adherent oxide film. Anodization is most commonly carried out in chromic acid solutions and sulfuric acid solutions. To improve corrosion protection, anodized coatings can be sealed in a second step in the process.

Chromic acid anodization is carried out in solutions that are at or slightly above room temperature. Coating times range from 30 to 60 min, and result in a 2–5-µm-thick gray-colored coating. This process does not consume much of the base metal, making it suitable for applications where precise part dimensions must be maintained. Among various anodization processes, the chromic acid process causes the smallest fatigue strength debit. The chromic acid process is the process of choice for porous surfaces and complex shapes where rinsing of the anolyte may be difficult. The residual anolyte is rich in chromate, which is passivating and protective for aluminum alloys.

Sulfuric acid anodization is carried out at ambient temperatures in  $\text{H}_2\text{SO}_4$  solutions. Coating times range from 30 to 60 min. The process yields coatings that are 5–10 µm in thickness. These coatings possess

**Figure 14** Backscattered SEM image revealing the anodized coating upon a sectioned piece of extruded AA6060. Courtesy of Brendan Stafford.

good corrosion resistance, which can be improved by sealing the coating through subsequent immersion in the sodium chromate solution. Coatings produced by this process can be dyed to take on a range of colors.

Changes to the sulfuric acid anodization process can be made to produce anodized layers with high hardness. The so-called hard coat anodization processes are carried out in solutions chilled to near freezing (about 1 °C). Coating times range from 20 to 120 min. These coatings can be as much as 50 μm in thickness. Coatings are very hard and suitable for applications where wear resistance is needed. The intrinsic porosity of the coatings makes them well suited for adhesive bonding applications. Corrosion resistance of these coatings is excellent and can be further improved by sealing in boiling water or nickel-based sealing solutions.

The protectiveness of anodized coatings is commonly tested using accelerated exposure testing. When anodized coatings fail, the substrate is subjected to localized corrosion, which occurs mainly in the form of pitting. Electrochemical methods are appropriate for characterizing the corrosion resistance of anodized coatings. In particular, electrochemical impedance methods are useful for determining the effectiveness of sealing treatments as well as the overall protectiveness of the anodized layer.

#### 3.08.6.4 Organic Coatings

The natural passivity of aluminum is often insufficient to protect against corrosion in many common

service environments. Alloying aluminum further degrades protection conferred by passivity, and alloys are almost always coated when the application requires prolonged exposure to outdoor environments.<sup>134</sup> A broad range of organic coatings can be applied to aluminum alloys. For many engineering applications, and certainly the most demanding ones, a coating system consisting of multiple coating layers is used. Each layer contributes to the functionality of the overall coating system. Functions imparted may include adhesion to the underlying alloy, flexibility, impermeability, chemical resistance, abrasion resistance, electromagnetic signature control and, of course, corrosion protection.

There are two general strategies for imparting corrosion protection by organic coatings: barrier protection and active corrosion protection. The barrier protection strategy is based on the simple concept of preventing contact of the underlying aluminum substrate with the environment. The vast majority of protective coatings systems used today are based on this concept. While simple and straightforward, this concept is remarkably difficult to implement and sustain in practice in engineered systems. There are two reasons for this. First, coatings contain defects that are formed during the application process. These defects can serve as corrosion initiation sites when a coated component is placed in service. In modern coating operations, great effort is made to apply coatings on scrupulously clean surfaces under very well controlled conditions. This minimizes defect

formation and leads to higher quality, longer lasting coating systems. Second, coatings will sustain damage in service. Damage can arise from mechanical action at the surface that scrapes or scratches. Damage can also arise by exposure to aggressive chemical agents. This can degrade the organic component of the coating destroying the barrier properties. Exposure to thermal energy and ultraviolet radiation can also degrade the integrity of the organic component of the coating.

In the active corrosion protection strategy, barrier properties of the coating are not necessarily important. Coatings that protect by this mechanism contain a releasable corrosion inhibitor. As moisture from the environment penetrates the coating, the corrosion inhibitor is released. In well-designed coatings, any moisture that reaches the coating-metal interface will have enough inhibitor in it so that the natural passivity of the underlying alloy is preserved. This protection strategy is not as widely employed as barrier protection, but strontium chromate-pigmented organic primer coatings used widely in aerospace applications depend critically on this protection mechanism.

Corrosion of aluminum under organic coatings generally occurs as filiform corrosion, although blistering is observed on samples exposed to accelerated corrosion tests or where coating adhesion is entirely inadequate. In thick and opaque coating systems, corrosion under the coating may be difficult to detect until corrosion has progressed to a significant extent.

Corrosion of organically coated metals is typically characterized using outdoor exposure tests or simulated service testing. Overaccelerated corrosion tests should be avoided, as their relative ranking of corrosion susceptibility is usually erroneous and the observed mode of corrosion is not that found in service. The extent of corrosion damage accumulation is normally characterized visually. Early stages of coating degradation and undercoating substrate corrosion can be characterized by electrochemical methods including electrochemical noise and electrochemical impedance spectroscopy. The application of impedance spectroscopy for characterizing degradation of organically coated metal surfaces has been thoroughly reported in the scientific literature.

### 3.08.7 Applications of Aluminum Alloys

In recent years, the aluminum industry has become a global industry, just as the business interests of its

customers have become global. The world economy has integrated, and major industry consolidation has occurred. Today, Alcoa is the only independent major producer in North America, as Alcan has become part of Rio Tinto. Alcoa, Alcan (as Rio Tinto Alcan) and Rusal are the three largest aluminum companies.

Total global aluminum consumption (as measured as aluminum semis, castings and forgings) grows each year by about 5% on average. Rolled products are the largest product form at 35% (16.4 mt) followed by castings at 26% (12 mt), extrusions at 24% (11.3 mt), wire and cable at 10% (4.8 mt), and forgings and other forms at 5% (2.5 mt). In 2005, the geographical market was split among North America (24%), Western Europe (22%), China (22%), Asia (21%), Latin America (5%), Africa and Oceania (2%), Eastern Europe (2%) and CIS (2%).<sup>3</sup>

Presently, there are three main markets for the aluminum industry: packaging (cans and foil), transportation (automotive and light trucks) and building and construction. About 25 years ago, building and construction was the largest aluminum market, packaging was second and transportation was third. Then, 10 years ago, transportation became the largest market, followed by packaging and then construction. However, more recently in the emerging economies, building and construction has been the greatest source of growth and this is now the second largest market for aluminum after transportation. In terms of global consumption of the 43 Mt of aluminum produced in 2005, transportation was 27%, building and construction 20% and containers and packaging 16%. These main uses were followed by electrical (10%), machinery and equipment (8%), consumer durables (7%) and other uses (12%). In 2007 ~14.5 Mt of aluminum was used in transportation, 13 Mt in building and construction, and 4.5 Mt in beverage cans.<sup>3</sup>

In packaging, aluminum cans are in competition with plastic containers and, to a much lesser degree, glass, although this varies considerably from country to country. In North America, steel is not much of a factor, whereas in Europe it still is, and in certain markets like the United Kingdom, there is direct and sustained competition between aluminum and steel cans. Presently, the recycling rate of aluminum used beverage cans (UBCs) varies significantly from country to country and from state to state in the United States. Critical factors are legislation and the use of financial incentives (e.g., returnable deposits on cans) to promote collection and return. Corrosion concerns in packaging applications are not a major factor.

There is a direct relationship between the weight of a car and its fuel consumption, and although there are global legislative initiatives to reduce fuel consumption and carbon emissions, the weight of cars has in fact progressively increased since the 1970s. This is shown by the increase in weight of the VW Golf from the Mark 1 (750 kg) to the Mark 2 (770 kg), the Mark 3 (960 kg), the Mark 4 (1060 kg) and the Mark 5 (1200 kg). The main factors that have led to this weight increase are safety, both for crash and pedestrians, comfort and build quality. The weight of a car is mainly from its structure or 'body-in-white' (BIW) (34%), its drive train (25%) and its engine (17%), and the increase in BIW weight has been the most significant contributor to vehicle's weight increase. There is strong competition between high-strength steel, aluminum, magnesium high pressure die castings and plastics for BIW construction. The average aluminum content of European cars increased from 32 kg in 1978 to 120 kg in 2002 and is predicted to be 160 kg by 2010. This total use of 160 kg is split between BIW hang-on panels (50 kg), suspension and wheels (50 kg), engine and drive train (43 kg) and interior components (17 kg). Audi has led the way in making aluminum-intensive cars exemplified by the A2 1.2TDi introduced in 1999, which was the first mass-producible car with a fuel consumption of 3 l of fuel per 100 km traveled. The emissions from this car were only 80 g of CO<sub>2</sub> per kilometer. In North America, it is estimated that an average car or a light truck has about 160 kg of aluminum and the major applications are in hang-on panels (bonnets and deck lids) and engines, with aluminum engines representing about 90% of current production. The potential for increased use of aluminum in cars is enormous, particularly as number of vehicles on the road is predicted to increase from 800 million to more than 1450 million in 2030 with nearly all of this increase in developing economies like India and China.

Forming and joining issues associated with the use of aluminum in cars have been solved, and the only reported corrosion issues have been galvanic corrosion where protection systems were not in place and filiform corrosion associated with rectification by grinding prior to painting. The main barrier remains the relatively high cost of aluminum automotive sheet as compared to its steel equivalent. Just as aluminum beverage cans compete favorably with steel cans through their high level of recyclability, it is the same for aluminum in transportation applications. Aluminum automotives become both cost and energy competitive with steel if the aluminum sheet

is recycled back to the same sheet and this is maintained over repeated construction and end-of-vehicle life cycles. Aluminum-intensive vehicles also offer increased vehicle life. Durability and corrosion issues associated with the use of recycled sheet will need to be addressed.

Although aluminum has enjoyed a dominant position as the material of choice for airframe construction, it has become increasingly threatened by composite materials. However, the overall tonnage of aluminum aircraft plate required by major manufacturers such as Airbus and Boeing is predicted to increase. For example, Airbus have estimated that their plate demand, which was 20.2 kt in 2002 and was 88 kt in 2007, will be more than 100 kt from 2010 onwards. Airbus consider the latest generation of aluminum lithium alloys such as 2050 with less than 2 wt% lithium to be competitive with composites for fuselage applications, and that their corrosion resistance is such that they can be used without cladding for fuselage skin applications. They are also considering an increased use of weldable alloys (AlMgSc) and using joining procedures like laser welding and friction stir welding to decrease the buy-to-fly ratio. The competition between aluminum plate and sheet and composites for airframe construction has stimulated the development of 2xxx, 7xxx (7449 and 7140) and 6xxx (6056) alloys with improved mechanical performance in terms of both strength and toughness. The development of improved alloys and the use of new joining techniques have stimulated significant corrosion-testing activity.<sup>135,136</sup>

### 3.09.1 Introduction

There is great concern about the weight of vehicles in automobile, aircraft, and aerospace sectors. With the existing rules of the European Commission on CO<sub>2</sub> emissions, the drive for a reduction in the consumption of petrol in automobiles has already be felt. A reduction in the weight of vehicles would not only help in minimizing the fuel consumption and emission levels, but would to a great extent enable the automobile and aviation industries to improve passenger and

transportation capacities, with considerable control of overall operating costs. However, it becomes essential to ensure passenger comfort and safety when such a design is being looked into.

So far, high-strength low alloy steels have a major share in the automobile industry, whereas age-hardenable aluminum alloys and titanium alloys mainly cater to the needs of the aircraft and aerospace sectors. With recent developments, the requirement for lightweight constructions can be fulfilled to a great extent by magnesium and its alloys. Magnesium alloys with lower density levels are destined to be the construction material in the aforementioned industries in the days to come. Weight savings of up to 30% could be achieved with magnesium in place of aluminum. This could be further improved by appropriate processing and additional treatments on magnesium alloys, and thus these alloys have a great potential for many applications. However, there are issues concerning magnesium alloys which limit their usage for critical applications. The low ductility of some of the alloys is one problem, and the galvanic corrosion of magnesium in contact with other materials is another big concern.

In this chapter, a comprehensive discussion of the magnesium alloys with reference to their classification, processing, and treatments is provided. The different forms of corrosion and their associated mechanisms, including environmentally assisted cracking, are dealt with in detail. The methods of combating the problems of corrosion, including some of the recent

advancements and modern practices, are addressed in the last segment.

### 3.09.2 Historical Perspective

Magnesium was discovered in 1808 by Sir Humphrey Davy. He achieved this by the electrolytic splitting of magnesium oxide with the help of cinnabar. Subsequently, different production techniques were developed by Bussy (1828), Liebig (1830), Bunsen (1852), and Sainte-Claire Deville (1857) for the extraction of magnesium, and magnesium found its first application as an explosive. Magnesium was first produced industrially by a procedure developed by Grätzel in an aluminum and magnesium factory at Hemelingen in 1886.

In 1896, magnesium was produced by molten bath electrolysis in a chemical factory in Bitterfeld. Until 1900, the global production of magnesium amounted to only 10 tons. With further developments, the production of magnesium rose steadily from 2200 tons in 1932 to about 14 000 tons in 1935. By 1939, this amount was doubled to 30 000 tons and then reached a level of 235 000 tons in 1943 owing to the high demand for materials during the Second World War. At the end of the war, the production dropped down again to 17 000 tons, with a more or less continuous increase in usage up to the present day. As of 2002, the global production of magnesium was around 400 000 tons per annum (Figure 1) and by the end of 2006 the

**Figure 1** Trend of global production and price of primary magnesium since 1937.

Source: <http://minerals.usgs.gov/minerals/pubs/commodity/magnesium/>

production of primary magnesium has been reported to be approximately 726 000 tons per annum.

In the early days, magnesium alloys were accepted by the automotive and aviation industry<sup>1</sup> owing to their light weight and good strength-to-weight ratio. In the 1970s, magnesium alloys were virtually forced out of applications owing to their poor corrosion properties and the low prices of aluminum alloys. Nevertheless, with increase in crude oil prices and stringent requirements from the environmental viewpoint (CO<sub>2</sub> emissions), magnesium alloys are experiencing a renaissance; they are popular today with wide acceptance and a large number of applications since the early 1990s.

### 3.09.3 Production and Types of Magnesium Alloys

#### 3.09.3.1 Extraction of Magnesium

Magnesium is the eighth most abundantly available element in the earth's crust, but it is not available in the metallic form in nature. **Table 1** shows the essential source materials for magnesium. Magnesite appears to be the most important ore of magnesium and is reported to be available with 95% purity level.

More than 50% of the global production of primary magnesium today is in China, and production installations are also found in Russia, Canada, Israel, Brazil, and the United States. In Australia and Congo, some projects are underway. Owing to the very high operating costs in the EU, no primary magnesium is produced there nowadays. Compared to the early stages in the 1980s when primary magnesium was sold at \$3.6 per kg, the prices touched \$2 per kg in 2002. However, with the increase in demand for raw materials, the prices have gone up again. Today, the primary production of magnesium is dominated by two routes *viz.*, (a) molten salt bath electrolysis and (b) thermal reduction. In the first case, MgCl<sub>2</sub> obtained from the source products is reduced by the electrolytic process, and in the thermal reduction process either dolomite or magnesite is processed with the addition of ferrosilicon. The composition and characteristics of some of the typical electrolytes used in the electrolytic reduction of MgCl<sub>2</sub> are provided in **Table 2**.

#### 3.09.3.2 Physical Metallurgy

While magnesium was primarily used as an alloying element for aluminum alloys in the early days, it took

**Table 1** Raw materials and their magnesium content<sup>2,6,7</sup>

		Percentage
Carnallite	MgCl <sub>2</sub> · KCl · 6H <sub>2</sub> O	8.7
Magnesite	MgCO <sub>3</sub>	28.8
Dolomite	MgCO <sub>3</sub> · CaCO <sub>3</sub>	13.2
Brucite	Mg(OH) <sub>2</sub>	41.7
Kieserite	MgSO <sub>4</sub> · H <sub>2</sub> O	17.6
Kainite	MgSO <sub>4</sub> · KCl · 3H <sub>2</sub> O	9.8
Forsterite	Mg <sub>2</sub> SiO <sub>4</sub>	17.3
Periclase	MgO	60.3
Sea water	MgCl <sub>2</sub>	0.5
Natural brines	MgCl <sub>2</sub>	3–10

until 2003 to reach the same level of use as a construction material (**Figure 2**). Other applications such as desulphurization of iron are also shown in the figure. The effect of alloying elements and important alloys of magnesium are introduced in the following sections. Most alloying elements form intermetallic phases with magnesium, resulting in either eutectic or peritectic systems. **Table 3** lists a group of binary alloys based on magnesium, indicating the solubility of alloying elements, the possible intermetallic phases, and also the melting point of each system.

The first industrially useable magnesium alloys were developed at the beginning of the twentieth century. The basic works at that time showed very clearly the influence of essential alloying elements on the property profile and the workability of magnesium alloys. The effect of alloying elements on the properties of a variety of magnesium alloys has been addressed in the literature.<sup>1–5</sup> An overview concerning the effect of the alloying elements on the properties is given in **Table 4**. **Table 5** shows the essential physical properties of pure magnesium and a very popular alloy containing aluminum and zinc, called AZ91. Furthermore, the chemical compositions of some of the commonly used alloys are provided in **Table 6**.

#### 3.09.3.3 Alloying Elements

Aluminum is considered as one of the primary alloying elements for magnesium alloys. The addition of aluminum to magnesium improves the strength and corrosion resistance, reduces the melting point and increases the melting range. Aluminum is also known to cause microporosity. In alloys containing more than 6% (by weight) aluminum, the intermetallic phase Mg<sub>17</sub>Al<sub>12</sub> (**Figure 3**) is formed. These alloys are heat

**Table 2** Typical electrolyte composition for electrolytic reduction of magnesium<sup>3</sup>

<http://www.intlmag.org>

treatable and thus an improvement in mechanical properties is feasible. Aluminum has no adverse influence on the weldability of magnesium. Nevertheless, aluminum in excess of 1.5% has been reported to increase the stress corrosion cracking (SCC) susceptibility of magnesium alloys. An aluminum content of about 10% favors fine grained solidification and also weldability. With regard to high temperature mechanical properties and creep strength, aluminum shows no positive effect.

Zinc is used, very often in combination with aluminum, in magnesium alloys. Because of its low melting point, the addition of zinc lowers the melting range of Mg–Al alloys, which on the other hand causes problems in solidification. A zinc content of more than 1% in magnesium alloys can lead to hot cracking problems during solidification, and a content higher than 2% can cause cracking during welding. Nevertheless, in combination with zirconium and/or thorium, zinc positively influences the mechanical properties. In addition, zinc improves the corrosion behavior of magnesium alloys.

Zirconium is used as a grain refiner in magnesium alloys which do not contain Al, Mn, Sn, Sb, Ni, Fe, Co, or Si or contaminants such as C, N, O or H. Zirconium helps in the development of a fine grain structure in the welding of magnesium alloys and in addition Zr minimizes the loss of ductility in welded joints. Furthermore, the presence of zirconium prevents excessive grain growth during heat treatment.

Alloying elements of the group of rare earth (RE) elements as well as thorium results in eutectic systems with limited solubility. The level of porosity is reduced in the presence of RE elements. In general, these elements form stable precipitates/intermetallic phases which improve the elevated temperature strength and creep resistance. In addition, an improvement in the

corrosion behavior is also observed with the addition of these elements. Yttrium is used as an alloying element along with RE elements. The other RE elements, *viz.*, Nd, Ce, La, and Pr, are often used in combinations. For example, the magnesium alloy designated as ‘QH21A,’ contains 2.5% Ag, 1.0% Th, 0.7% Zr, and 1.0% Di. Didymium (Di) consists basically of about 85% Nd and 15% Pr.

Beryllium has a very low solubility in magnesium; nevertheless, it has great potential to control the melt oxidation while melting or welding. However, the addition of beryllium needs to be done very carefully as it may cause grain coarsening. As a rule, the addition of beryllium should be restricted to a maximum of 30 ppm in magnesium alloys.

Additions of calcium in quantities >0.03% will increase the susceptibility to hot cracking. During solidification, the calcium-rich low melting eutectic mixture wets the grain boundaries, consequently leading to cracking assisted by the solidification stresses. In aluminum containing magnesium alloys, calcium additions lead to the formation of a stable intermetallic phase Al<sub>2</sub>Ca in preference to

Mg<sub>17</sub>Al<sub>12</sub>, which helps in improving the high temperature properties.

The addition of strontium in small quantities is reported to reduce the porosity during welding of high pressure die cast alloys, as it improves the solubility of hydrogen. Further, in conjunction with RE additions, strontium is found to improve the high temperature properties of magnesium alloys.

Silicon improves the castability if added in small quantities. With addition of up to 1% it forms the high-melting intermetallic phase magnesium silicide (Mg<sub>2</sub>Si) and thus improves the high temperature properties. However, in the presence of iron it deteriorates the corrosion resistance of magnesium to a great extent. Higher silicon content (>1%) in magnesium alloys decreases the castability drastically because of primary precipitation of Mg<sub>2</sub>Si in the melt.

Lithium can be used in large quantities in order to reduce the density of magnesium even further. Besides, an increase in Li content beyond 11%, leads to a change in the crystal structure from hexagonal close packed to body centered cubic structure. With the availability of more slip systems, the formability of the alloys is greatly improved, but the strength of Mg–Li alloys is generally reduced. Further, the problems of burning and vaporization arise while melting in presence of higher levels of lithium. In addition, the corrosion resistance of magnesium alloys in presence of lithium has been reported to be poor.

Manganese is found in most of the magnesium alloys. Primarily, manganese in magnesium alloys improves the ductility, and as it forms stable compounds with iron and other alloying elements, the corrosion resistance is improved on account of control of ‘free’ iron. Manganese also has a positive effect on the weldability and shows some grain refinement effect, too.

Copper has been reported to improve the high temperature properties of magnesium alloys. At the same time, Cu levels greater than 0.05% have been found to be highly detrimental for the corrosion resistance of the magnesium alloys. Other elements with similar adverse effect on the corrosion resistance of magnesium alloys are, Fe, Ni, Cr and Co. However, they are generally regarded as impurities in magnesium alloys.

### 3.09.3.4 Alloy Designations

As for ferrous systems, there are quite a number of alloy designation systems for magnesium alloys, too. An overview of the universally accepted alloy designation for magnesium systems, as recommended by the German Institute for Standardization (DIN) and

**Table 4** Selection of alloying elements and their effect on properties of magnesium alloys<sup>13</sup>

RT – room temperature.

the American Society for Testing of Materials (ASTM) is provided below.<sup>3,4,6</sup> As per the German Institute for Standardization (DIN) EN 1754 the materials receive a prefix EN M followed by the marking of the product form as below:

- A: Anodes (Ingots)
- B: Block metals
- C: Castings

After this marking, the chemical composition is provided. Therefore, the marking EN M C MgAl9Zn1 is the designation for a magnesium alloy casting with 9% Al and 1% Zn.

The identification of magnesium alloys is also standardized worldwide by the ASTM standards; each alloy is marked with letters indicating the main alloying elements, followed by the rounded figures of each element in weight percentage. Table 7 shows the key letters for each of the available alloying elements. The last letter in each identification number indicates the stage of development of the alloy (A, B, C, etc.). The alloy AZ91D, for example, is an alloy with a rated content of 9% aluminum (A) and 1% zinc (Z). Its development stage is 4 (D). The corresponding DIN specification would be MgAl9Zn1.

ASTM specifies the following composition for the above designation D (all values wt%): Al 8.3–9.7; Zn 0.35–1.0; Si (max.) 0.10; Mn (max.) 0.15; Cu (max.) 0.30; Fe (max.) 0.005; Ni (max.) 0.002; others (max.) 0.02.

Some of the alloy designations may also contain the history of heat treatment. The designation of heat treatment follows the rules of aluminum alloys.<sup>3</sup> The purpose of the heat treatments in the case of magnesium alloys would be to achieve the desired microstructural state and properties. The different temper designations concerning the heat treatment of magnesium alloys are presented in Table 8.

### 3.09.3.5 Cast Magnesium Alloys

The first commercial magnesium alloys, among them many AZ systems, were developed in the mid 1930s, and in recent times significant developments have taken place on alloy development. Even though new alloys have been developed with specific properties viz., high strength, creep and corrosion resistance etc., the AZ system of alloys still remains as the prime group. These alloys are of importance because of good casting properties, especially in high pressure die casting, and in general these alloys possess a good combination of properties. The main alloying elements are aluminum and zinc, with both the elements improving the castability. Alloys belonging to the category of AM designations, with Al and Mn as the major alloying elements, have relatively inferior castability. However, these alloys have better toughness and reasonable strength. Both these categories of alloys are suitable for both cold and hot chamber pressure die casting. Nevertheless, the properties of the AZ and AM series alloys are highly insufficient for applications at temperatures higher than 130 °C.<sup>7</sup>

For elevated temperature applications (>130 °C), AE and AS categories of alloys are preferred, in which the RE elements or silicon, respectively, are the essential alloying elements in addition to aluminum. These alloys have poor castability, and owing to the high melting points and formation of precipitates in the melt, the alloys are not suitable for hot chamber high pressure die casting. These alloys can successfully be employed at temperatures up to 180 °C.

Other alloys for high temperature applications are available in the WE, ZE, or QE systems. The WE group of alloys contains yttrium and RE elements as main constituents are currently used in the aviation industry, e.g. for gear cases in helicopters. They can be used up to temperatures of 300 °C.<sup>8–10</sup> While the alloys of the ZE system are based on zinc and RE elements, the QE alloys are based on silver and RE elements. These alloys are processed predominantly by sand casting and are not suitable for high pressure die casting. The processing capabilities of these alloys in the semisolid state have not yet been fully understood. Further, both the above systems are not used any more for major industrial applications. The newly developed alloys MRI, AJ, and ACM appear to be superior compared to the old ZE and QE type of alloys for the high temperature applications, as can be seen from Tables 9 and 10.

All aforementioned alloys are used nowadays in the form of high purity alloys. The level of impurities in

the magnesium alloys is of great importance from the viewpoint of corrosion resistance. Even small levels of nickel, iron or copper as impurities may adversely influence the corrosion behavior of magnesium alloys. These elements are controlled in the primary processing stages, for example, by the addition of elements like manganese to form an intermetallic compound with iron. The high purity magnesium alloys offer a

much superior corrosion resistance compared to those with intolerable levels of impurities.<sup>8</sup>

A new trend in alloy development is to check the current alloys on their ability to be processed in the semisolid state and to modify them for better semisolid processing. The modification is done by additions of calcium, strontium and also RE elements. These elements have been reported to improve the

mechanical properties and corrosion behavior as well.<sup>10,11</sup> The RE elements especially improve the mechanical properties at high temperatures due to formation of stable precipitates. Thus, the creep behavior is strongly improved.<sup>12–14</sup>

Unlike aluminum alloys, grain refiners for use with magnesium alloys are not well known. Only a few elements such as Zr, Sr, Si and C are known as effective grain refiners.<sup>1,3,15,17</sup> Zirconium works only in magnesium alloys which are free from Al, Si, Sn, Mn, Sb, Ni, Fe and Co. In such alloys Zr addition has been reported to provide finer grain size and this

contributes to better formability. Particles such as SiC can work as grain refining agents as well.<sup>17</sup> However, none of the mechanisms for the grain refinement of magnesium alloys is completely understood. Most of the grain refiners work only in certain alloys and combinations of them may influence the effectiveness or may even have an opposite effect.<sup>2,3,17</sup>

Magnesium castings are also produced by squeeze and thixocasting techniques. In the first case, the material is handled in a completely molten state and in the latter it is processed in a semisolid state. The squeeze cast magnesium alloys exhibit a good strength and ductility, owing to the fact that the squeeze casting develops fine grained structures.<sup>18</sup> Even though the squeeze cast alloys are expected to exhibit good fatigue behavior, their creep properties are poor, essentially because of the fine grains. Properties of semisolid processed alloys are still under investigation. As the main applications are housing for electronic components, the property requirements are not that stringent for these alloys.

### 3.09.3.6 Wrought Magnesium Alloys

Wrought magnesium alloys have a great potential for light weight construction, especially in the automobile

industry, owing to the excellent strength to weight ratio. For rolling into sheet alloys, low levels of alloying elements are generally used (e.g., AZ31), while for extrusion and forging, basically, all alloys can be used. The AZ family of alloys with low zinc content and different levels of aluminum is the dominant alloy system, as they exhibit an attractive combination of strength and ductility. The increase in aluminum content in the alloy leads to an increase in the secondary phase content ( $Mg_{17}Al_{12}$ ), which in turn results in increased strength levels with acceptable drop in ductility. In the wrought systems, the most commonly used alloys are AZ31, AZ61, and AZ80. Furthermore, Mg–Mn alloys (M1 and M2) are used for extrusions. The advantage is the high press rate; however, the

ductility is rather low, hence this alloy system is of less importance.<sup>19</sup> Other alloys used are based on the Zn system (ZK30, ZK60) in which Zr is working as grain refiner and providing an improved formability to the material. Furthermore, typical cast alloys of the AZ (AZ91) and AM (AM50, AM60) systems are used mainly for extrusions,<sup>20–22</sup> and also for forgings. The WE system (WE43, WE54) has also gained commercial importance in extrusions and forgings in recent times. The mechanical properties of typical wrought alloys are given in [Tables 11 and 12](#).

### 3.09.3.7 Magnesium Matrix Composites

In addition to conventional magnesium alloys, metal matrix composites (MMCs) based on magnesium are studied to extend the field of applications. MMCs, as they are defined, contain at least 5% of strengthening phases/constituents in the alloy matrix. The secondary strengthening constituents may be present in the form of long fibers, short fibers, whiskers or particles and in addition, a mixture of particles and fibers is also feasible. Generally, all magnesium alloys can be used as matrix material, but in view of the intended applications, the heat-resistant alloys are mostly used as matrix.

The MMCs have been reported to possess higher specific strength than the monolithic magnesium alloys. MMCs have shown better properties in terms of Young's modulus, thermal expansion coefficient, electrical and thermal conductivity and creep resistance.<sup>23,24</sup> The creep rates of the magnesium MMCs are reported to be about 10–100 times lower than those of the monolithic alloys, and in fact these MMCs are believed to compete with some class of steels in terms of creep properties. However, corrosion resistance is most of the time adversely affected because of galvanic effects between the reinforcement

and the matrix. Nonconducting reinforcements are generally a better choice to minimize the galvanic corrosion attack.

### 3.09.4 Processing of Magnesium Alloys

#### 3.09.4.1 Casting Technologies

About 95% of the magnesium components are produced by liquid metallurgy route, and the processing temperatures are normally in the range of 600–800 °C. Magnesium and its alloys are extremely reactive in the molten state and extreme care is required for protecting the melt. In the early days, salt-fluxes were used to protect the melt, and in addition these are useful to clean the impurities in the melt, to some extent.<sup>1</sup> However, today, these fluxes are seldom used and the modern foundries, which process magnesium alloys mostly employ controlled atmospheres. In the beginning, a mixture of inert gases, e.g. N<sub>2</sub>, with SF<sub>6</sub>, was used for protection,<sup>25,26</sup> with SF<sub>6</sub> offering an efficient protection against oxidation to the molten baths up to temperatures of around 700 °C by forming a thick protective film. However, since 2007, the use of SF<sub>6</sub> has been restricted on account of environmental regulations. SO<sub>2</sub> has been recommended by the European Commission as an alternative to SF<sub>6</sub>. However, SO<sub>2</sub> is a toxic gas, and handling it is more

**Table 11** Mechanical properties of forged magnesium alloys<sup>9,10</sup>

difficult than SF<sub>6</sub>; thus, the magnesium producers are exploring the possibilities of employing SO<sub>2</sub> on the production scale.

Sand casting belongs to the traditional casting techniques and was already employed for magnesium in the early days, but the problems that were encountered are partly unsolved up to now. The exothermic reaction between the components of sand (silicon dioxide, iron oxide, and water) and molten magnesium can damage the mould and the surface of the component. In order to minimize this problem, sulfur, boric acid, calcium fluoroborate, ammonium fluorine silicate and urea (referred to as inhibitors) are used individually or in combination.<sup>1,4</sup>

For gravity die casting, moulds from steel are normally used. Even though the problem of reaction between the mould and the molten metal does not arise in this case, the steel moulds are expensive, and the surface finish is rather inferior. However, generally good quality casting can be produced by gravity die casting procedure, if the wall thickness is high enough. Thin walled parts are better produced by pressure assistance.

Magnesium components are produced predominantly by pressure die casting techniques and both the cold and hot chamber die casting procedures are adopted in the industry. Both techniques yield components with fine grain structure, excellent quality surface finish and a greater dimensional accuracy. The major disadvantage of these techniques, however, is the inevitable gas inclusions in the castings, preventing the use of heat treatments to fully utilise the potential of the alloys. Employment of either cold or hot chamber technique for the production of castings depends also on the type of alloys. AZ91, AM50 and AM60 alloys are most suitable for the production of castings by hot chamber pressure die casting technique. The AS and AE systems of magnesium alloys, which have relatively higher melting points than the

**Table 12** Mechanical properties of wrought magnesium alloys<sup>40</sup>

AZ or AM alloys, are more suitable for casting in cold chamber pressure die casting machines. The latter can also be used for processing AZ and AM based alloys.

Squeeze-casting is a special process with a vertical arrangement of a slewable casting unit and molding direction. When the unit is filled, it closes and docks to the mould. Then, the piston rises up and the actual filling begins. In contrast to die-casting, the molding is done slowly (minimum turbulence and hence low porosity), though the final compression is the same. In squeeze-casting, however, the pressure is maintained until freezing is complete and even allows for further feeding in the semi-solid condition. Injection pressures are usually between 70 and 100 MPa, so as to obtain a compact and fine-grained microstructure. Squeeze-casting is an excellent method for producing pressure-sealed, low-porosity, weldable, heat-treatable parts with reproducible high quality. It is increasingly being used in place of classical gravity casting. Magnesium alloy casting can be made by employing both direct and indirect squeeze casting techniques and the same is applied for the production of MMCs, too.

Thixocasting is a fairly new method based on the thixotropic properties of semi liquid alloys. The material while processing would reach the liquidus temperature and would consist of a mixture of solid and liquid phases (also known as semi-solid metal forming). For example, intense stirring can be used to prevent the usual formation of dendritic grains, instead, globular grains form. This condition is characterized by thixotropic flow behavior; with increasing viscosity the shearing strain falls off. The actual procedure requires suitably manufactured raw material. Technically, it is carried out by electromagnetic stirring (rheocasting) within a slab-casting machine.

Recently, much effort has been directed towards shortening the time required for the electromagnetic

stirring so as to lower the processing costs. A first step towards this goal is the so-called NRC process (new rheo-casting process). This process tries to avoid dendritic growth by a customized melting-cooling process and simultaneous turning of the melting crucible. The advantages of this procedure compared to conventional casting are as follows: (a) complete automation of the production process, (b) high productivity, (c) cost savings due to low energy consumption, (d) higher tool lifecycles, (e) parts free from gas inclusions and hence weldable, (f) low cooling shrinkage and no blow holes, (g) parts with excellent mechanical properties, and (h) final parts with near-net-shape quality.<sup>27–30</sup> Even though all the three procedures, NRC, thixocasting, and thixomoulding can process the material in the partially liquid state, the source, state, pretreatment and realization of the process differ in each case.<sup>31</sup> Thixocasting, in general, promises improved mechanical properties and comparable wall strengths for magnesium alloy components compared to high pressure die castings.<sup>32,33</sup> Microstructures of some of the commercial alloys in the various cast conditions are presented in [Figure 4](#).

### 3.09.4.2 Forming Technologies

The three major metal forming processes that are widely employed for the processing of magnesium alloys are (a) rolling, (b) extrusion, and (c) forging. The deformation behavior of magnesium alloys is greatly influenced by a number of variables, *viz.*, crystal structure, initial microstructure, thermodynamic conditions, state of stress, method of deformation etc. At ambient temperatures, the formability of magnesium alloys is limited, owing to the hexagonal close packed structure. However, with increase in temperatures to about 225 °C a higher number of slip systems becomes active and an improved metal forming behavior is observed.

**Figure 4** Optical micrographs of some cast magnesium alloys.

Magnesium alloy sheets have to compete with aluminum and steel sheets for automotive applications, offering at least the same economical and technical benefits. For economic reasons, rolling is preferred to be done at temperatures as close as possible to ambient temperature. However, considerable optimization is required for obtaining sheets with acceptable mechanical, thermal and corrosion properties and surface finish.<sup>34</sup> The surface quality is controlled by the use of appropriate lubricants, either oil based or solid lubricants like molybdenum disulphide.<sup>35</sup> The anisotropy that is observed in the magnesium alloy sheets can be minimized by appropriate use of thermo-mechanical treatments and the choice of alloys.

The coarse grained structure of magnesium cast alloys can be readily converted into fine grained ones by hot working processes, such as extrusion. The mechanical properties of the extruded alloys depend on the chemical composition and the thermo mechanical pretreatment that is given to the alloys.<sup>36</sup> The extrusion processes have three variants, *viz.*, direct extrusion, indirect extrusion and hydrostatic extrusion, but most commonly used industrial processes are direct and indirect extrusion. Cylindrical ingots are heated to 300–400 °C depending on the alloy and pressed through matrices with manifold cross-sections. The maximum extrusion length is 50 m. Because of the required complexity, only AZ31 or M2 alloys with restrictions, and AZ61 alloys

as well, can be extruded with economical speed, the minimum wall thickness that could be achieved is determined by the alloy and the type of profile. For small to medium-sized AZ31 profiles, the minimum wall thickness that is achievable is 1.2 mm.<sup>37,38</sup> Hydrostatic extrusion is still under examination, but it seems to allow higher extrusion rates and lower extrusion temperatures. Representative micrographs of typical wrought alloys are shown in [Figure 5](#).

Magnesium alloy components can also be produced by forging. However, there are limitations in terms of availability of suitable alloy systems, formability and corrosion behavior of these alloys. Nevertheless, wheel rims have been successfully forged and used in commercial vehicles and racing cars.

### 3.09.4.3 Joining Technologies

The joining technologies for magnesium alloys can generally be classified into two broad categories, *viz.*, mechanical fastening and metallurgical bonding. Screwed connections, riveted joints and use of adhesives form the first group, and the second group is constituted by fusion or solid state joining processes, *viz.*, power beam welding, friction stir welding, diffusion bonding, etc.

An overview of the different aspects of preparing screwed connections for magnesium alloys was given by Weissert.<sup>39</sup> It is important to bear in mind the different thermal expansion coefficient values of

**Figure 5** Optical micrographs of wrought magnesium alloys (extruded).

magnesium and steel/aluminum when designing components for elevated temperature operation (especially above 100 °C) in a multi-material mix design. From the design and the material selection perspective, it is necessary to ensure that the screwed/bolted assemblies do not lose their pre-stress during application, and the materials chosen as screw do not foster galvanic corrosion. The latter can be minimized by the right choice of material combinations, appropriate coatings, and constructive measures.

Welding is one of the most widely used joining technologies for magnesium alloys. The weldability of magnesium alloys is influenced by (a) chemical and physical properties, (b) chemical composition, and (c) production process, and the quality of base material. The physical properties that are considered relevant for welding are the melting point, the boiling point, the thermal conductivity, and the coefficient of thermal expansion. A wide solidification range in the alloys, increases the possibility of hot cracking as well as the localized melting of some of the eutectic phases in the alloy.

Joining of magnesium alloys can be accomplished by different fusion welding processes *viz.*, gas tungsten arc welding, gas metal arc welding, plasma arc welding, laser beam welding and electron beam welding. Solid state joining processes *viz.*, friction welding, friction stir welding, and diffusion bonding are also employed for this purpose.<sup>40–42</sup>

Even though the gas tungsten arc (GTA) and gas metal arc (GMA) welding are still popular,<sup>43–45</sup> with the advent of power beam processes and friction stir welding, the trend moves towards the modern techniques for the joining of magnesium alloys.<sup>46,47</sup> The GTA and GMA welds suffer from the inherent drawbacks of large weld pool/heat affected zone, low welding speeds and higher degree of distortion and residual stress. In some cases, hybrid welding with laser and GTA/GMA combination has proved to be successful for achieving

deeper penetration welds in magnesium alloys,<sup>48</sup> also overcoming some of the issues mentioned above. Recently, the activated-GTA (popularly called as A-TIG) with flux addition was employed for the welding of AZ31B, and full penetration joints in 5 mm thick plates were claimed to have been realized with acceptable quality.<sup>49</sup>

The absorption of laser beam on the surface of materials being joined plays a crucial role in the case of magnesium alloys, and this has been treated extensively in literature.<sup>50,51</sup> Even though both CO<sub>2</sub> and Nd:YAG lasers are employed for welding of magnesium alloys, the weldability with Nd:YAG has been reported to be much superior due to shorter wave length and stable molten pool.<sup>52,53</sup> Quite a large number of researchers have investigated the evolution of microstructures and the mechanical properties of magnesium alloy laser beam welds.<sup>54,55</sup> The mechanical properties of the resultant weldments were observed to be dependent on the alloy composition, and a wide range of property variations have been reported for these weldments. However, in almost all the cases, a distinct reduction in the fracture strain values of the weldments was reported. Also, the electron beam welding of magnesium alloys is attempted by researchers, especially, for welding of higher section thickness magnesium alloys.<sup>47</sup>

The application of the friction stir welding process for joining of magnesium alloys is described in the literature.<sup>4,56</sup> The development of this modern solid state joining technique has given a new dimension to the joining of the so-called difficult to weld aluminum and magnesium alloys. However, in contrast to the aluminum alloys, the published literature on the characterization of friction stir welded joints of magnesium alloys is quite limited.<sup>57–59</sup> The investigations made and documented so far, suggest, that there exists a great potential for employing FSW for making not only similar, but dissimilar welds containing

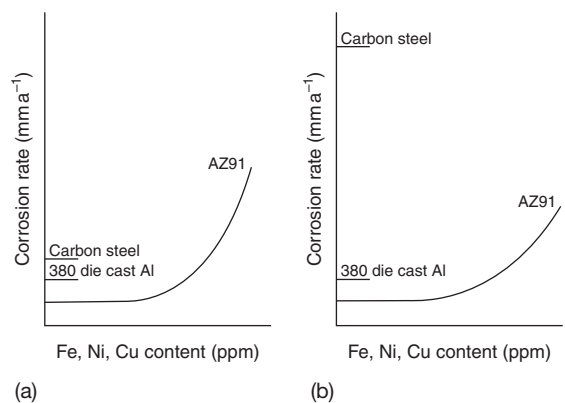

**Figure 6** Microstructural features of a friction stir weldment.

magnesium alloys, as well. The macrostructure and the microstructural features of the parent and weld nugget regions of the friction stir weldment of AZ61 alloy are depicted in [Figure 6](#).

### 3.09.5 Corrosion of Magnesium Alloys

Until recently, it was believed that magnesium has a poor corrosion resistance amidst the metals and alloys known to the engineering industry. This widespread view was essentially owing to a variety of reasons which include, but are not limited to: (a) poor alloy design (with higher levels of impurities like Fe, Ni, and Cu, and or inclusions of melting salts), (b) improper design of the components, or (c) none or a wrong or inadequate surface protection for the chosen application. But, today's magnesium alloys show corrosion properties similar to or better than some of the structural grade carbon steels and copper-containing high strength aluminum alloys ([Figure 7](#)). With the right choice of alloy and the developments in the field of surface engineering, the so-called 'susceptible magnesium' alloys are nowadays used for a variety of applications in the electronic, automobile and aircraft industry with appropriate surface protection.<sup>60–63</sup>

**Figure 7** Corrosion rates of AZ91 die cast alloy with different impurity levels. (a) In salt spray test and (b) atmospheric exposure at the Brazos River on the Texas Gulf Coast for 2 years.

On the one hand, the uniform or general corrosion of magnesium alloys in various environments is relatively well controllable, whereas on the other hand, the galvanic corrosion and the environmentally assisted cracking (SCC and corrosion fatigue) are the causes of failures of components made from these alloys. Other forms of corrosion such as pitting corrosion, filiform corrosion, and crevice corrosion apparently play an assisting role in the damage.

Intergranular corrosion of magnesium alloys does not seem to happen because of the fact that the grain boundaries outlined with secondary phases are nobler than the matrix/interior grains.

### 3.09.5.1 Forms and Mechanisms

Like all the metals which do not exist in the metal state in nature, magnesium has to be extracted from its ores, requiring considerable quantum of energy. Hence, magnesium also tends to return to its stable natural state by reactions with elements of the environment, that are mainly oxygen and water. Magnesium has a standard electrode potential of  $-2.37$  V for bare magnesium in contact with a solution containing Mg divalent ions, and is the most active construction material in the EMF series (Figure 8). Its free corrosion potential in neutral chloride solution is around  $-1.7$  V *versus* SCE, and is in the active end of the galvanic series (Figure 9). The shift of the potential is caused by the polarization due to passive film formation.

The fact that magnesium reacts instantaneously with air and water leads to the formation of corrosion products on the surface. The nature of the layer is determined by the surrounding environment, and in many instances, this leads to a reduction of the corrosion rate due to the effect of passivation, which by itself is an effective corrosion protection means. Thus, in normal atmospheres, the level of corrosion damage on magnesium alloys is insignificant. However, with increase in relative humidity of air the extent of corrosion damage in general increases. At low ambient humidity magnesium reacts with the oxygen of the air to form magnesium oxide ( $\text{MgO}$ ), which forms as a thin passive layer on the surface of the material. In more humid conditions ( $>93\%$  relative humidity) first, a surface layer of magnesium hydroxide ( $\text{Mg(OH)}_2$ ) develops, which subsequently

converts into magnesium carbonate ( $\text{MgCO}_3$ ) as a result of the reaction with the  $\text{CO}_2$  in the air. In marine and industrial atmospheres, chlorides, sulfates, and nitrates can destroy this protective layer and may induce corrosion damages.

In aqueous solutions, the process of corrosion of magnesium, which is dependent on the pH and temperature, is described below:

The dissolution of magnesium is the partial anodic reaction

and/or

and the hydrogen evolution is the partial cathodic reaction

The following cathodic reaction can lead to the evolution of hydroxyl ions

The potential–pH diagram, known as the Pourbaix diagram, for the system magnesium–water is shown in Figure 10. It is obvious from this diagram that magnesium undergoes active dissolution in the pH range from 0 to 11, and magnesium hydroxide is stable only above pH 11. In contrast to aluminum, magnesium forms stable and self healing passive oxide/hydroxide layers in aqueous solutions without additional ions, only if the pH values are higher than 11. Immunity, the state in which corrosion cannot take place due to thermodynamic reasons, exists only below  $-2.5$  V, because of the very low negative standard potential of magnesium. Nevertheless, the corrosion rate is normally very low in small sealed off water volumes because of the low solubility of  $\text{Mg(OH)}_2$  (the saturation equilibrium is reached fast), and owing to the dissolution of magnesium, a pH value above 10 is quickly reached. However, if the exchange of water becomes constant, this equilibrium will not be reached and the corrosion progresses continuously. An increase in temperature also accelerates the corrosion rate.

In aqueous chloride solutions with heavy metal ions such as Ni, Fe, and Cu, the corrosion rate of magnesium alloys is generally very high. These metal ions will be deposited on the anodic magnesium surface and act as very active cathodes, thus driving

Figure 8 Electromotive force series (EMF series).

**Figure 9** Free corrosion potentials of metallic materials in neutral sodium chloride solution.

**Figure 10** Potential-pH diagram (Pourbaix diagram) of Mg-H<sub>2</sub>O system.

magnesium to dissolve at a rapid rate by galvanic action. Various anions, too, have an effect on the localized dissolution of magnesium hydroxide, and chlorides play a much more prominent role than sulfates and nitrates. However, there is a group of anions that help in the formation of a protective

layer on the surface, upon forming hardly soluble and adherent compounds with marginal dissolution of magnesium. Such salts are used in the electrochemical surface treatment of magnesium alloys (fluorides, chromates, vanadates, phosphates, etc.). Dissolved oxygen in water or salt solutions has no additional corrosive effect.

As magnesium is stable in solutions with pH > 11, due to a stable  $Mg(OH)_2$  layer, it does not corrode in alkaline solutions. All acids, except HF and  $H_2CrO_4$ , tend to attack and dissolve magnesium strongly. In the aforementioned exemptions, the formation of a stable film upon initial dissolution helps in preventing further dissolution. An aqueous chromic acid ( $180 \text{ g l}^{-1}$ ) solution is often used to clean magnesium alloys from corrosion products.

Most of the organic compounds (aliphatic and aromatic hydrocarbons, ketones, ether, glycol, etc.) have very little effect on the corrosion of magnesium alloys. The corrosion effect on magnesium alloys by ethanol is rather light, and anhydrous methanol inflicts a strong attack. Sour liquids like fruit juices, carbonated drinks, milk, etc., also cause measurable corrosion attack.

The resistance of magnesium alloys to almost all gases, including the aggressive chlorine, is very good

as long as the gases are dry. Even very small quantities of humidity lead to the formation of acids and hence, may result in a strong damage to the magnesium alloys, for example, in the presence of chlorine and sulfur dioxide. In contrast, the performance of magnesium alloys in ammonia containing atmosphere is good, regardless of whether the conditions are dry or humid. The oxidation of magnesium in the presence of oxygen increases with temperature; however, the applications at elevated temperatures are limited mostly by the creep resistance and not by the oxidation rates. As mentioned earlier, the corrosion performance is dependent on the pH value, and apparently the corrosion performance of magnesium alloys in soils depends on the pH value of the soil. Thus, the corrosion rate is higher in saline acidic soils than in neutral or alkaline soils.

Because of the basic nature of magnesium alloys with very active corrosion potentials, the corrosion is accelerated when in contact with other metals due to the galvanic effect. This is taken as an advantage for applications, wherein, magnesium alloys are used as sacrificial anodes for the cathodic protection of metals. However, for structural applications in aggressive media some additional coating and/or constructional measures are required on components to be protected.

The compatibility of magnesium (so-called anodes) and a second metal (cathodes) to be used as a couple in a given environment, is determined by the potential difference of the couple and the polarization resistance. In principle, these potential differences should be as low as possible and the resistance polarization (of the cathode material) should be as high as possible. Aluminum alloys belonging to the 5XXX and 6XXX series are the most compatible materials due to a relatively low potential difference with magnesium, compared to most other acceptable materials. Interestingly, despite a very large potential difference 80Sn/20Zn alloy coatings are also acceptable because of their high polarization resistance characteristics. The following materials are absolutely not acceptable to be used as a direct couple with magnesium alloys: practically all steels, nickel and aluminum alloys containing copper. However, in the case of steels, a coating of zinc plus a cataphoretic painting to the tune of 15  $\mu\text{m}$  would be helpful for making a couple with magnesium alloys.

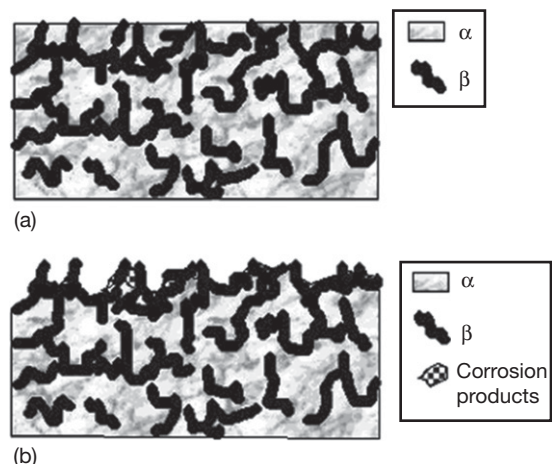

Magnesium alloys are not only susceptible to galvanic corrosion when in contact with other metals, but also for a special kind of galvanic corrosion in the form of so-called ‘microgalvanic cells’. The potential differences between the anodic and cathodic regions

within the alloy is the reason for this type of corrosion that can occur in chloride-containing neutral as well as in alkaline media. Impurities such as iron, copper, and nickel, although mostly present as intermetallic compounds in the matrix, have very noble potentials compared to the matrix and thus, accelerate the corrosion damage of the matrix. The corrosion damage can at times be highly localized and lead to pits. The effect is similar in alloys containing the secondary phase  $\text{Mg}_{17}\text{Al}_{12}$ , wherein the regions with this intermetallic compound exhibit more noble potentials than the matrix in chloride solutions. The same effect can be observed for almost all intermetallics, formed between magnesium and alloying elements.

Even though the galvanic drive is expected to accelerate the dissolution of the surrounding matrix, it is feasible to tailor the properties of magnesium alloys with proper distribution of the secondary phase in the matrix. For example, in pressure die cast alloys with fine grained structure, the distribution of  $\text{Mg}_{17}\text{Al}_{12}$  secondary phase can be made more favorable, and this phase can form a coherent corrosion barrier network along the grain boundaries (Figure 11),<sup>65</sup> and thus, may lead to lowering of the corrosion rate.

### 3.09.5.2 Environmentally Assisted Damages

The term environmentally assisted cracking, in general, refers to failures under conditions of either static or dynamic loading with considerable assistance from

**Figure 11** Schematic representation of the change of surface conditions during corrosion of a magnesium alloy with nearly continuous  $\text{Mg}_{17}\text{Al}_{12}$  phase near to the surface.<sup>65</sup> (a) Initial surface and (b) final surface.

the environment. In the case of statically loaded components, this failure is influenced by the dissolution of the alloy, known as SCC, or induced by the entrapped/picked up/generated hydrogen at the tip of the crack, referred to as hydrogen induced cracking (HIC), or hydrogen embrittlement (HE). Under conditions of cyclic loading, the failures that happen with the influence of the environment are termed as corrosion fatigue (CF).

SCC is generally considered to be a dangerous form of damage, as it often leads to catastrophic failures. The mechanisms of SCC vary from one system to the other, and mechanistically SCC is quite subtle. The failure under these circumstances can be without any signs of visible deterioration of surfaces, but can happen due to highly localized damage. In fabricated components, apart from the external stresses, the residual stress in the components itself can lead to failures. The SCC susceptibility of wrought magnesium alloys has been widely looked at by researchers. Nevertheless, cast Mg alloys too, have been reported to be susceptible to SCC, especially when the stress levels are higher.

The SCC behavior of magnesium alloys is very similar to that experienced in the metals/alloys with a passive layer. There has always been a debate, as to whether pure magnesium is susceptible to SCC or not<sup>66–70</sup>; however, the alloys of magnesium are susceptible to this form of damage to a great extent. Stampella *et al.*<sup>70</sup> reported the susceptibility of 99.95% (high pure) magnesium to SCC in sulphate solutions based on slow strain rate tensile (SSRT) tests. The susceptibility of magnesium alloys to SCC was reported based on the laboratory tests performed by numerous researchers and compiled by Winzer *et al.*<sup>71</sup> SCC of a variety of magnesium alloys was observed in environments containing very low concentrations of (as low as 0.001 N) sulfates or chlorides or even in distilled water. Further, SCC has been observed in chromate containing solutions.

A fairly large amount of work has attempted to understand the effect of alloying elements on the SCC behavior of magnesium alloys. Aluminum, one of the major elements for strengthening, has been reported to adversely influence this behavior, with the threshold concentration level of around 2.5%.<sup>69,70</sup> Higher aluminum containing alloys have been found to fail by SCC, even in distilled water. Miller<sup>72</sup> reported that zinc increases the SCC susceptibility, which was contradicted by Fairman and Bray.<sup>73</sup> Surprisingly, the manganese containing magnesium alloys are generally considered to be immune in the atmosphere, chloride

solutions, and chloride–chromate solutions,<sup>72</sup> but have been reported to be susceptible in distilled water.<sup>74</sup> Addition of cadmium and neodymium to Mg–Zn–Zr alloy has been reported to improve the SCC resistance<sup>75</sup> and, conversely, the deleterious effect of Cd was also reported.<sup>69</sup> The presence of Fe as impurity plays a crucial role in SCC, especially in the impure alloys. The presence of intermetallic compounds such as FeAl is reported to influence the SCC,<sup>76</sup> the micro galvanic effect in these alloys leads to stronger hydrogen evolution, and the cracking is expected to be with the assistance of hydrogen.<sup>77,78</sup>

In a recent work, the SCC susceptibility of an extruded magnesium alloy (AZ31) in ASTM D 1384 test solution (Figure 12) was addressed.<sup>79</sup> The fracture was observed at a stress level of around 100 MPa with a strain of 2% compared to the strain level of about 45% in the tests in air. The fracture surfaces of SSRT tested AZ31 magnesium alloy (in air and in ASTM D 1384 solution) presented in Figure 13 show characteristic fine dimples in the specimen tested in air, and a distinct transgranular cleavage fracture in the specimen tested in ASTM D 1384 solution.

The documented literature on the SCC of magnesium alloys suggests that in a majority of the cases the failure was transgranular (TG) in nature. SCC of magnesium alloys in intergranular (IG) or mixed modes are also reported in literature.<sup>80,81</sup> The differences in fracture modes have been attributed to the heterogeneities at the grain boundaries, leading to the formation of micro galvanic cells and subsequent dissolution along the grain boundaries, thus resulting in IGC.

**Figure 12** Stress–strain plots of SSRT tested AZ31 magnesium alloy.<sup>79</sup>

**Figure 13** Fracture surface appearance of SSRT tested AZ31 alloy ( $10^{-6} \text{ s}^{-1}$ )<sup>79</sup>: (a) in air and (b) in ASTM D 1384 solution.

**Figure 14** Continuous crack propagation by dissolution following film rupture.<sup>82</sup>

**Figure 15** Model for transgranular cracking in Mg-Al alloys.<sup>83</sup>

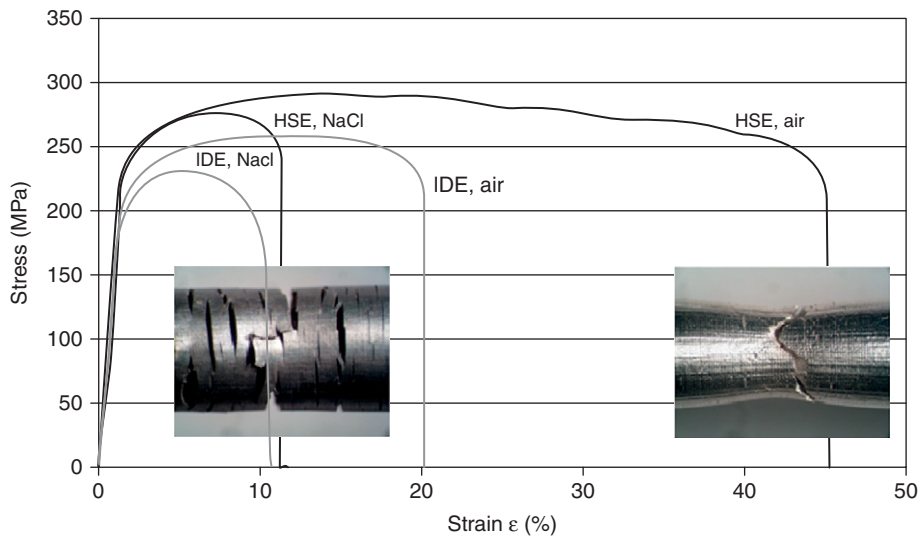

The SCC propagation mechanisms for magnesium alloys fall in one of the following two groups: (a) continuous crack propagation by anodic dissolution at the crack tip (Figure 14)<sup>82</sup> or (b) discontinuous crack propagation by a series of mechanical fractures at the crack tip (Figure 15).<sup>83</sup> The dissolution mechanisms could be (a) preferential attack, (b) galvanic attack by film rupture, or (c) tunneling. The mechanical fracture mechanisms are broadly either (a) cleavage fracture or (b) hydrogen embrittlement. A comprehensive description of the SCC mechanisms in magnesium alloys can be found in the review by Winzer *et al.*<sup>71</sup>

There is not much published information on the effect of processing conditions on the cracking susceptibility of magnesium alloys. The data presented in Figure 16<sup>84</sup> suggests that the processing

conditions have a definite influence on the mechanical properties of AZ31 alloy. However, it is interesting to note that the strain to failure of the specimens in chloride environment is nearly the same although the difference in air is quite large.

The information on the SCC behavior of welded magnesium alloys is also quite scarce. Welds produced by the modern joining technologies *viz.*, friction stir welding and laser beam welding, seem to have good mechanical properties. The SCC of laser and friction stir weldments addressed recently,<sup>79</sup> suggest that the fusion boundary region is susceptible to SCC. A mixed mode of fracture (transgranular + intergranular) has been reported in both these weldments subjected to SSRT tests in ASTM D1384 solution, and further, the

**Figure 16** Effect of processing conditions on the SCC of AZ31.<sup>84</sup> IDE – indirect extrusion; HSE – hydrostatic extrusion.

**Figure 17** Stress-strain plot of SSRT tested friction stir weldment of AZ31.<sup>79</sup>

weldments showed a higher susceptibility to SCC than the parent alloy (**Figures 17 and 18**).

Cathodic polarization of magnesium alloys is reported to reduce or even prevent SCC of magnesium alloys in aqueous solutions.<sup>66,70,72</sup> However, yet in another recent work,<sup>85</sup> it has been found that AZ80 alloys undergo SCC–HE under conditions of continuous charging under cathodically polarized conditions in distilled water. **Figure 19** shown below explains the effect of cathodic charging on the cracking behavior. The exact role of hydrogen and the precise underlying mechanisms of SCC under such conditions are still being debated.

**Figure 18** Fracture surface appearance of FSW weldment of AZ31.<sup>79</sup>

### 3.09.5.3 Influence of Alloying and Processes

The corrosion behavior of magnesium alloys is influenced substantially by the impurities. The heavy metals contained as impurities (*viz.*, Fe, Cu, and Ni) form galvanic cells and enhance the corrosion rate, and the effect of these impurities on the corrosion rate is depicted in **Figure 20**.<sup>86</sup>

The tolerance limit depends on the alloy composition. For pure magnesium, the tolerable limits for Cu, Fe, and Ni are 0.1%, 0.005%, and 0.0005%, respectively. These impurities in magnesium alloys arise from various sources; the iron pick up is primarily from the melting crucibles and tools, copper comes from impure aluminum, while nickel gets in

**Figure 19** Stress-strain curve of AZ80 alloy at a strain rate of  $10^{-6} \text{ s}^{-1}$ : in air; preexposed in distilled water for 24 h and then immediately strained in air; precharged at  $\sim 300 \text{ mV}$  cathodic to the open circuit potential (OCP) for 24 h in distilled water and then immediately strained in air; continuously charged at  $\sim 300 \text{ mV}$  cathodic to OCP in distilled water during the test.<sup>85</sup>

**Figure 20** Effect of impurities on the corrosion rate of magnesium alloy AZ91.<sup>86</sup>

from nickel containing stainless steel crucibles or at times very low levels of Ni may be contained in the raw magnesium itself.<sup>87</sup> If these impurities are restricted within tolerable limits, a substantial improvement in the corrosion resistance of magnesium alloys could be accomplished.

Magnesium alloys in which the total content of these impurities is restricted to 'ppm' levels are referred to as high purity (HP) alloys, and these alloys can virtually compete with aluminum alloys in terms of corrosion resistance.<sup>86</sup> In the salt spray tests performed as per ASTM B 117, the high purity magnesium alloys (with the exception of AM20) showed very low corrosion rates, (Figure 21)

**Figure 21** Comparison of corrosion rates of HP magnesium alloys and  $\text{AlSi}_9\text{Cu}_3$ . (Note the corrosion rate of AZ91 with impurities beyond the tolerable limits.)

compared to a silicon and copper containing aluminum alloy (AA4250), which is used as a secondary alloy in the automobile industry.

The micro galvanic effects, as well as the formation of passive layers to minimize the corrosion can be influenced by addition of specific alloying elements. Besides the production of HP alloys, the susceptibility to corrosion of magnesium alloys can be controlled by the addition of RE elements. It is believed that these elements stabilize the passive film formed on the surface of magnesium alloys. In addition, the intermetallic phases formed in the magnesium alloys containing SE, show corrosion potentials similar to the aluminum containing matrix and thus, eliminate the galvanic effect. Additions of manganese to magnesium alloys help in reducing the galvanic corrosion, as manganese preferentially forms an intermetallic compound with aluminum, incorporating Fe and Ni, thus bringing down the effect of potential differences between free iron or nickel and the magnesium matrix in the alloys. The tolerance limits for impurities (especially Fe) in such alloys can be higher, without many of its problems. Aluminum improves the corrosion resistance in magnesium alloys when the alloying addition is increased from 2% to 9%. The benefit is two fold, first,  $\text{Mg}_{17}\text{Al}_{12}$  forms a favorable corrosion resistant network along the grain boundaries, and second, the incorporation of aluminum oxide in the  $\text{Mg}(\text{OH})_2$  layer improves the stability of the passive layer and thus enhances the corrosion resistance. Owing to the superior passive layer on the surface in aluminum containing magnesium alloys, a special form of corrosion, so-called filiform corrosion, is observed which is otherwise observed only underneath thin coatings. Zinc increases the corrosion potentials and thus reduces the corrosion rate. Also, the elements such as zirconium added as grain refiners to magnesium alloys can influence the corrosion behavior positively.

The microstructure with a given grain size and precipitate has a great influence on the corrosion resistance. Small grain size is often reported to be more corrosion resistant than larger grains. Thus, corrosion resistance can be optimized by the choice of the production process. So, the same alloy processed with HPDC has generally a better performance than sand or gravity die casting, and this can be explained by higher cooling rates resulting in a finer microstructure. Using special melt or powder metallurgical production processes or thermo mechanical treatments, even smaller grain size can be obtained. The new production processes, such as semi-solid processing, result in specific microstructures and thus have an influence on the corrosion performance. The globular microstructure with surrounding intermetallic phases is often reported to have good corrosion resistance. The best corrosion resistance, however, is often found with the products of rapid solidification processes. Precipitates and impurities are often finer and more uniformly distributed or the alloying elements remain in solid solution without forming precipitates. Passive films on supersaturated alloys are more easily formed and are more uniform and stable. In Mg–Al alloys, the  $\beta$ -phase ( $\text{Mg}_{17}\text{Al}_{12}$ ) formation can be suppressed by rapid solidification, and there is sufficient Al available to stabilize the passive layer by the formation of  $\text{MgAl}_2\text{O}_4$  spinels.<sup>88</sup>

Heat treatment of magnesium alloys influences the corrosion behavior, as the involved diffusion process has an effect on the distribution of alloying elements in the matrix and also influences the secondary phase formation. In general, magnesium alloys subjected to heat treatment (solution treatment, ageing, etc.) exhibit a higher corrosion rate when compared to the as-cast condition. The latter is especially the case if the precipitates have a barrier function in the as-cast condition, owing to the formation of a dense network along the grain boundaries.

### 3.09.6 Corrosion Prevention Strategies

#### 3.09.6.1 Coatings

Magnesium and magnesium alloys can hardly be protected by alloy development against general corrosion in acidic environments and against galvanic corrosion. Instead, for this purpose, a wide variety of coatings are available. The coatings are also used for improving the aesthetic appeal and for increasing the decorative finish. The following techniques are

available for the surface modification of magnesium and its alloys:

- Chemical conversion coatings  
Chromating, phosphating
- Electro-chemical coatings  
Anodizing  
Electroplating (Zn, Cu, Ni, Cr)  
Plasma electrolytic oxidation
- Physical techniques  
Physical vapor deposition  
Plasma/laser assisted vapor deposition  
Thermal spraying
- Nonmetallic coatings  
Varnish, wax, polymeric coatings, paints.

The physical techniques are still in the research stage, and only the other surface modification technologies are adopted in the industry to some extent as of today. A detailed overview, description of the processes, and information about the advantages and disadvantages of many surfaces treatments for magnesium alloys is given by Gray and Luan.<sup>89</sup> Before selecting a coating system for a given application, it is necessary to understand the corrosion behavior of the magnesium alloy in question in the service environment and the suitability of the material for processing, to deposit the coating. The surface preparation plays a crucial role in making the coating system perform well in the field of operation.

A number of problems are specific for coatings on magnesium alloys. No coating system polarizes magnesium in the cathodic direction, since all the coatings are more noble than the magnesium alloy matrix. Coating of magnesium, especially with a metallic coating, may lead to an accelerated galvanic attack in aqueous environments, if the deposited layers are not sufficiently thick enough or if there are any defects/damages in the coatings. However, magnesium surfaces can be modified and effectively protected by multilayered systems. For reasons of cost, the coating system is mostly decided, based on the aggressiveness of the environment and the application demand. Pickling, conversion coating, anodizing, plating, and organic coatings are available and multiple combinations of these are possible.

##### 3.09.6.1.1 Chemical conversion coatings

Chromating is a known surface treatment for aluminum, zinc, and magnesium for years and this treatment develops a very thin layer (to about 1  $\mu\text{m}$  maximum). The treatment can be used for the prevention of damage by corrosion of magnesium alloy

components during storage and transport. In addition to corrosion protection, these films offer an inhibitive effect inherent to the chromate film. The adhesion to organic coatings is also greatly improved by this treatment.<sup>90</sup> Nevertheless, the use of chromates is limited by the new environmental regulations in Europe since 2003, owing to growing health concerns associated with hexavalent chromium.<sup>91,92</sup>

New alternatives to the chromating process based on phosphate permanganate or fluoride zirconate have been proposed.<sup>90</sup> Alternate chrome-free conversion coatings based on alkali potassium permanganate solutions (MAGPASS-COAT<sup>®</sup>) and from solutions containing vanadates, molybdates and tungstates have also been attempted.<sup>93,94</sup> As these conversion coatings impart good adhesion properties, a few attempts have been made to produce chrome-free coatings in electrolytes based on stannates<sup>95</sup> and RE salts.<sup>96</sup> Effort was also made to produce conversion coatings based on zinc manganese phosphating electrolytes on magnesium alloys.<sup>97</sup> In general, all these conversion coatings need to be used in combination with an overlay coating for efficient corrosion protection, especially in aggressive environments.

#### 3.09.6.1.2 Electrochemical conversion coatings

The anodic oxidation of magnesium alloys result in a relatively thick and electrically insulating layer with good wear resistance. Like the chemical conversion coatings, the anodic oxide films also provide a good base for organic coatings, and in addition these can be impregnated as well. In particular, the newer processes are capable of developing very hard ceramic layers (ANOMAG<sup>®</sup>, KERONITE<sup>®</sup>, TAGNITE<sup>®</sup>, and MAGOXID<sup>®</sup>). These treatments are carried out in electrolytes at higher operating voltages with low current density levels leading to a plasma discharge.<sup>98</sup> The temperature of the bulk electrolyte tends to rise, typically to around 50 °C (depending on the degree of cooling provided to the system). The local temperature in the plasma zone would probably be in excess of 1000 °C, this results in the formation of 'glassy' or 'ceramic' anodic coatings. The process is called by various names, *viz.* plasma anodizing, micro arc oxidation (MAO), and plasma electrolytic oxidation (PEO).

The composition and the thickness of the conversion layers developed, depend on the processing conditions, *viz.* the chemical composition of the alloy, electrolyte composition, operating voltage, current density, temperature of electrolyte, duration, etc.

The thickness of the layers ranges from a few microns to as high as 150 µm. Electrolytes containing combinations of hydroxides, carbonates, silicates, phosphates, aluminates, and borates have been explored. The processing voltages are in general a function of the composition of electrolytes, and voltage levels as high as 600 V are achieved during this PEO processing. The current density for the PEO operation ranges generally from 5 to 50 mA cm<sup>-2</sup>, which is decided depending on the electrolyte/material combination. A few of the conventional and plasma anodizing processing electrolytes, processing conditions and resultant films are presented in Table 13.<sup>99</sup>

Figure 22 represents schematically a typical PEO coating obtained in an electrolyte based on silicate and hydroxide. The various zones that are observed in the PEO coatings are: Zone 1 (interface): The interface is very rough. It appears as if there were thin layers of less than 1 µm thickness with a finer and more dense structure in the interface region; Zone 2 (micro porosity): This has an extension from 20 to 80 µm. Here, the ceramic oxide film is denser, and only a small number of larger pores or cavities are visible; Zone 3 (pore band): This is observed in all specimens and can be identified by a pronounced band of cavities at a depth of 20–40 µm from the surface. Most of the visible surface pores (craters with discharge channels) seem to end in this band of cavities; Zone 4 (near surface): This is the outermost surface with the crater structure on the top. The ceramic layer is enforced by a large number of discharge channels reaching from the crater surface toward Zone 3. The porosity is the most striking feature of the anodized layers (Figure 23), and the size and distribution of pores strongly influence the properties of the layers. It should be noted that the other coatings can vary from this layered structure.

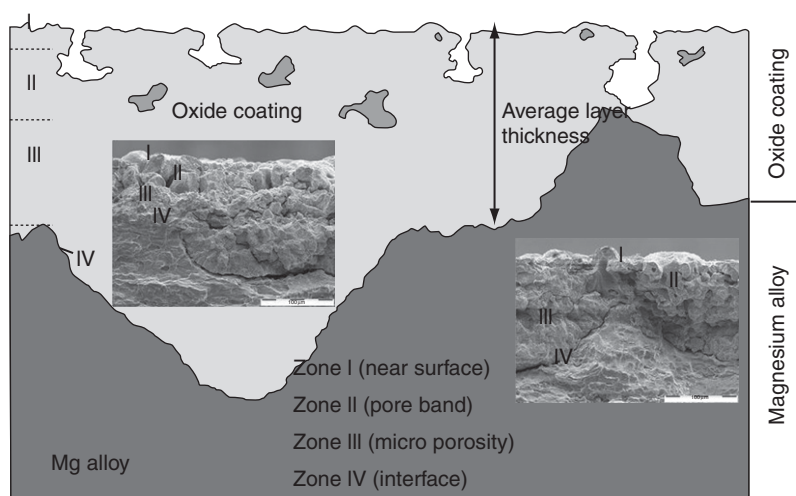

As almost all PEO layers are more or less porous, a secondary seal coat would be preferred for an enhanced corrosion protection, depending on the environment in which the components are to be used. However, their use in the commercial market as of date, is somewhat restricted owing to the high operating costs associated with the processing.

#### 3.09.6.1.3 Electro and electroless deposition

The deposition of metals and/or alloys from aqueous solutions containing the respective metal salts is practiced for many of the components made of both ferrous and nonferrous metallic substrates for imparting better surface finish, aesthetic appeal, corrosion resistance, electrical conductivity, solderability etc.

**Table 13** Some commonly used anodic oxidation processes for magnesium alloys<sup>99</sup>

Process	Electrolyte Components	Current density ( $A\ cm^{-2}$ )	Type of current	Electrolyte temperature ( $^{\circ}C$ )	Layer color
HAE	Potassium fluoride Sodium phosphate Potassium hydroxide Aluminum hydroxide Potassium permanganate	1.5–2.5	AC or DC	27	Brown
DOW 17	Ammonium difluoride Sodium dichromate o-Phosphoric acid	0.5–5.0	DC	70–80	Green
AHC Magoxid-Coat®	Mineral acid (fluoric, phosphoric, boracic acids)  Organic matters	1–5	Special types of signals with plasma-chemical reaction	15–20	White

**Figure 22** Schematic representation of a typical cross section of PEO-coated magnesium alloy.<sup>100</sup> (Typical features of the scanning electron micrographs inserted.)

There is not much older literature on the established practices for the deposition of metals/alloys on magnesium, but recently the interest manifested in the number of publications is increasing, especially in China.

There are lots of issues in the deposition of metals/alloys on magnesium alloys. First, magnesium is quite active and can react with oxygen to form a layer on the surface which very strongly inhibits effective deposition. Hence, it calls for a specific and careful preplating treatment procedure. Second, magnesium undergoes active dissolution in acidic or near neutral solutions upon immersion, and hence needs to be handled carefully while plating. Nevertheless, there have been a number of research attempts for the prevention of

corrosion of magnesium by plating techniques. Plating of nickel/gold has proved to be good for some space applications, while plating with silver was rated good from electrical conductivity. Plating of gold is reported to be done in stages with the first stage being zinc immersion plating, followed by nickel electro flash and finally the gold coating.<sup>101</sup> Recently, in an interesting work, plating of zinc from ionic solutions was demonstrated by Bakkar and Neubert and it is claimed that deposits were free from defects and showed corrosion behavior (Figure 24) similar to that of pure zinc in chloride solutions.<sup>102</sup>

Electroless nickel plating is also contemplated for magnesium alloys with a careful pretreatment of the substrates. In order to promote better coating

**Figure 23** SEM image showing the topography of the PEO-coated magnesium alloy.<sup>100</sup>

characteristics, magnesium surfaces may be given a zinc or copper flash coating over which nickel can be deposited by the electroless technique,<sup>98</sup> and the deposition of flash coating is similar to that performed for the deposition of gold. The electroless nickel deposits are harder than most of the magnesium alloys ( $\leq 80 \text{ HV}_{0.1}$ ), in general to about  $500 \text{ HV}_{0.1}$ . Such coated magnesium alloys find applications in electronics and telecommunications, guaranteeing a stable electrical contact with good resistance to adhesive wear and corrosion. It is mandatory to ensure that the deposits are free from pores and cracks as these defects can very adversely influence the corrosion behavior of the coated magnesium alloy (galvanic effect), despite the presence of a layer intended for protection. Further, recycling of such coated alloys is not feasible, especially if one looks at the production of high purity magnesium alloys. This is true despite the fact that there are quite a number of stripping solutions available for the removal of coatings from magnesium substrates.

#### 3.09.6.1.4 Physical techniques

Advanced techniques like laser beam (LB) and electron beam (EB) processing offer large scope for the modification of the surface of engineering alloys. Thus, magnesium alloys can be tailored by just heating to critical temperatures, or remelting with or without the addition of alloying elements, or by depositing coatings (cladding).

The thermal spray coatings often have a good amount of porosity, and this could be a major disadvantage from the corrosion point of view. The modern thermal spray techniques like high velocity oxy fuel or detonation gun spray process could produce effective coatings as the porosity levels are substantially low.

**Figure 24** Potentiodynamic polarization behavior of WE43 magnesium alloy with and without Zn electrodeposit in 0.1 M NaCl solution.<sup>102</sup>

Thermal spray coatings on magnesium alloys have been reported for space applications.<sup>103</sup>

With the LB, EB and thermal spray processing, surfaces resistant to wear and corrosion can be produced by means of alloying and diffusion and it is even feasible to develop functionally graded layers. The physical and chemical vapor deposition technologies can also be used for coating a number of metallic and ceramic layers on magnesium alloys. The advantage and disadvantage at the same time is that they can be used economically only for reinforcement of smaller local areas whereas large area coatings are normally too time consuming. The coatings that can be achieved by thermal sputtering in highly controlled atmospheres are free from oxidation, and it is possible to produce thin and thick corrosion resistant protective coatings depending on the requirement.

Laboratory scale experiments on chemical vapor deposition (CVD) of molybdenum are reported to improve the corrosion resistance significantly, by the formation of a stable thin film ( $<0.5 \mu\text{m}$ ) of molybdenum on magnesium alloy substrates.<sup>104</sup> Deposition of titanium nitride and zirconium nitride by plasma assisted CVD have also been attempted.<sup>105</sup> PVD coatings based on Mg alloys can be used for cathodic protection of conventional magnesium substrates.<sup>106–108</sup> However, the applicability of PVD and CVD coatings on large scale industrial components has not yet been fully explored.

#### 3.09.6.1.5 Organic coatings

The effect of organic coatings is generally to prevent or reduce the contact of water, oxygen, or other electrolytes with the metal surface. They are generally used in combination with conversion or anodized

coatings and offer in this combination an excellent corrosion protection (paint). If they are used alone, then normally only a temporary protection is intended, for example, the use of wax or oil for storage or shipping. The most important aspect for the selection is a resistance against alkaline corrosion products of magnesium alloys.

### 3.09.6.2 Choice of Coating Systems and Design Aspects

The damage caused by galvanic corrosion of the magnesium components in contact with other metallic materials can also be reduced or fully suppressed by employing appropriate constructive measures. The most effective method is to avoid the accumulation of electrolyte in the area of contact of materials, as this virtually eliminates the formation of a galvanic cell.

The other way of controlling the galvanic corrosion of magnesium alloys is to control the cathodic reaction so that the net anodic reaction (galvanic attack) on magnesium can be reduced correspondingly.<sup>109</sup> The galvanic current ( $I$ ) is expressed as

$$I = (E_C - E_A)/(R_C + R_E + R_M)$$

where  $E_C$  and  $E_A$  are the open circuit potentials of the cathode and anode, respectively,  $R_M$  and  $R_E$  are the resistances of the metal circuit and the electrolyte, respectively, and  $R_C$  is the cathodic polarization resistance.

Based on the above equation, the net galvanic current flow can be controlled by selecting an appropriate and compatible material as a couple, thus keeping the potential difference as low as possible. By using suitable coatings and insulation materials, the resistances  $R_C$  and  $R_M$  can be increased, resulting in lower galvanic current. As mentioned earlier, keeping the electrolyte away will result in an increased  $R_E$ , hence, in that case, too, a better galvanic corrosion resistance can be expected.

The choice of protective systems for magnesium alloys depends on the size, shape and geometry of the components and the joining technologies employed. Screwed and riveted joints offer the most varied possibilities to control, as one can alter the anode, cathode and the electric contact between these as well as the contact with the electrolyte. In some cases, by providing insulation between the magnesium and the other contacting material, the magnesium component can be left as such without any coating. There have been instances in which failure of a coating on

magnesium alloys led to accelerated form of damage by the galvanically driven corrosion.

Conventionally galvanized steel screws can be employed with a silicate sealing for fastening of magnesium alloys, and it has been proven to be successful for applications in commercial vehicles.<sup>110</sup> The steel screws can also be electroplated with an alloy deposit of 80%Sn–20%Zn for a better performance.<sup>111</sup> The steel fasteners can also be used with nylon or plastic caps as cover for the screw heads.<sup>109</sup> In addition, washers made of an aluminum alloy (6XXX series, anodized) or polymer can be used with steel screws to minimize the galvanic corrosion. The use of Al screws instead of steel, if the loading conditions are not that severe, is a good idea. Fiber reinforced plastic screws on PEEK base with carbon or polyamide fibers can also be used considering the fact that the polymers are free from galvanic corrosion.<sup>112</sup>

The surface treatment procedures described above can also be applied for the treatment of magnesium alloy weldments. In principle, these weldments can be treated as an individual component; however, it is well known that the heat affected zones could be the vulnerable region in the weldments.<sup>113</sup> Nevertheless, by appropriate selection of processing parameters, a good protection from corrosion damage can be offered to these weldments.

### 3.09.7 Applications of Magnesium Alloys

Magnesium alloys have had applications since the early 1930s, when they were first used in the cast form in automobiles. Since the start of its production in 1939, more and more parts, such as the crank case, camshaft sprocket, gearbox housing, several covers, and the arm of an electric generator, were added, until the total magnesium weight reached 17 kg in 1962, which meant a reduction of 50 kg in total mass compared to steel. The production of the VW Beetle used almost 21 000 tons of magnesium alloys in 1960,<sup>114</sup> and the Volkswagen Group reached a total consumption of 42 000 tons of magnesium alloys in 1972,<sup>115</sup> until the change from air-cooled to water-cooled engines reduced the use of magnesium alloys. Other manufacturers used magnesium in their technical applications as well as in complex parts such as tractor hoods made of die-castings (dimensions: 1250 mm × 725 mm × 480 mm; weight 7.6 kg), main gear boxes for helicopters (casting weight 400 kg, machined 200 kg), crank cases for zeppelin engines, air intake cases for propjet engines (weight 42 kg), frames,

rims, instrument panels, fan blades for cooling towers (weight 169 kg), etc.

The development of high purity (HP) alloys, with their much improved corrosion resistance, contributed to the rapidly expanding production. In the past, the corrosion behavior of the available alloys had often been the overriding factor preventing their application. The factor favoring the use of magnesium is that it counts as a substitute for polymers for which no satisfactory recycling solution has yet been found. Furthermore, it allows light-weight construction for reduced energy consumption or simply easier handling.

With regard to the processing of magnesium alloys, pressure die-casting is preferred in view of its advantages compared to the processing of aluminum and zinc, which are both amenable to this type of casting. Besides the specific properties of magnesium mentioned above, the other favorable factors

are its low casting temperature (650–680 °C, depending on the alloy) and the relatively low energy needed for melting. The energy needed for AZ91 ( $2 \text{ kJ cm}^{-3}$ ) is about 77% of that required to melt the aluminum alloy AlSi12CuFe.<sup>116</sup> The high price of magnesium usually refers to its mass not its volume, and the lower density coupled with other factors can actually make it cheaper in real terms. Thus, the low thermal heat content allows the casting process to be 50% faster than with aluminum; a high clock cycle of parts is possible, maintaining high precision and good surface quality.

Thus, magnesium can be found in a variety of applications today. The density, its shielding against electromagnetic radiation, and the possibility of producing thin-walled parts has led to furthering the use of magnesium die-cast parts in the computer industry, in mobile phones (Figures 25(a) and 25(b)), and in hand tools (e.g., chainsaws).

**Figure 25** Applications of magnesium alloys in the communications sector.<sup>122</sup> (a) Parts for a telephone switch board and (b) a mobile case.

**Figure 26** Applications of magnesium alloys in automobiles.<sup>122</sup> (a) Fuel tank cover in Mercedes Benz and (b) gearbox housing in VW-Passat (Volkswagen AG).

Other examples of magnesium parts in vehicles include:

- gearbox housing, e.g., in the VW Passat, Audi A4
- the inner tailgate in the Lupo ('3-liter car'), which was made of AM50 (3.2 kg)
- tank cover in the Mercedes-Benz SLK
- cylinder head caps, for example, made of AZ91HP by cold-chamber high pressure die casting, and having a weight of 1.4 kg<sup>117</sup>
- dashboard, for example, in the Audi A8 and in the Buick Park Avenue/Le Sabre<sup>118</sup>
- seat-frames<sup>119</sup>
- steering wheels, for example, in the Toyota Lexus, Celica, Carina, and Corolla<sup>118</sup>
- rims, for example, in the Porsche Carrera RS (9.8 kg AM70 HP; low-pressure ingot casting).<sup>117</sup>

The list of magnesium parts in cars could be further continued<sup>120,121</sup> and new examples are constantly being added. Two recent applications of magnesium are illustrated in **Figures 26(a) and 26(b)**. The Mercedes-Benz SLK fuel tank cover is used as an example to show the advantages resulting from converting the construction from conventional materials to magnesium alloys. The part supports the car body and serves as a separation between the trunk and the back seats. Previous solutions consisted of a welded conduit frame. The first alternatives were steel and aluminum welding (7–8 kg each) and a magnesium cast part. The magnesium casting could be established as a serial part with a total weight of 3.2 kg, a decreased spatial requirement, and fewer components. Moreover, no post processing was necessary and the part could be used uncoated. The use of magnesium in the gearbox housing in the VW Passat is also primarily based on the weight savings achieved by replacing aluminum alloys. The use of the AZ91 alloy instead of aluminum led to a total weight reduction of almost 25%, and the geometry and production equipment remained identical.

### Glossary

**Adsorption** The surface retention of atoms, molecules, or ions by a solid or a liquid.

**Alloy** A metal product containing two or more elements as a solid solution, intermetallic compound, or mixture of metallic phases.

**Anatase** A tetragonal polymorph of titanium dioxide, also called octahedrite.

**Cathodic modification** Enhancement of cathodic kinetics by alloying additions leading to depolarization of the cathodic reaction and a shift of the corrosion potential to the passive region.

**Complexation** Formation of a coordination compound between a metal ion and a molecular or ionic entity known as a ligand.

**Corrosion allowance** An excess amount of metal included in a component, beyond that required for mechanical considerations, to compensate for expected corrosion losses.

**Creep** Slow, time-dependent strain of a solid caused by stress.

**Diffusion coefficient** The mass of a species, in grams, diffusing across an area of 1 cm<sup>2</sup> in

one second in a unit concentration gradient. Also known as diffusivity.

**Environmentally-assisted cracking** A cracking process driven by tensile stress in the presence of particular favorable environmental conditions (e.g., stress corrosion cracking, hydrogen-induced cracking).

**Film fracture events** Spontaneous and sudden rupture of the passive film on a metal, resulting in exposure of the underlying metal to the environment.

**Fretting** Wear and corrosion damage at the asperities of contact surfaces induced by repeated relative surface motion under load.

**Galvanic coupling** The joining of two dissimilar metals in an electrolyte, potentially leading to galvanic corrosion.

**Halide** The anion of an element belonging to the halogen group (F, Cl, Br, I, At).

**Hydriding** The formation of a covalent compound between hydrogen and a metal

**Hydrolysis** The reactions of metal cations with water to produce oxides or hydroxides and increase acidity.

**Initiation** The start of a localized corrosion process.

**Intermetallic compound** A covalent compound of two or more metals, or the alloy of two metals in which a progressive change in composition is accompanied by a progression of phases, differing in crystal structure.

**Lamination** A layered arrangement.

**Load** The mechanical force that is applied to a body.

**Metallosis** Infiltration of metal ions and/or particles into, and inflammation of, soft and/or bony tissues proximate to metallic biomedical implants as a result of wear, corrosion, and/or hypersensitivity reaction.

**n-Type** A semiconductor whose electrical conduction is associated with electrons (as opposed to holes) as the majority charge carrier.

**Nitinol** A TiNi shape-memory alloy.

**Propagation** The active stage of ongoing reaction and damage formation during a localized corrosion process.

**Repasivation** The cessation of corrosion and return to passivity of a surface after loss of passivity caused by localized corrosion or mechanical damage.

**Rolling** Reducing or changing the cross-sectional area of a workpiece by the compressive forces exerted by rotating rollers.

**Rutile** A tetragonal polymorph of titanium dioxide.

**Semiconductor** A solid material whose electrical conductivity is intermediate between that of a conductor and insulator, and is usually strongly temperature-dependent.

**Stress intensity factor** A measure of the stress at a point in a structure due to pressure resulting from combined tensile and compressive stresses.

**Texture** The anisotropic ordering of size, shape, and crystallographic orientation of grains in a polycrystalline solid.

**Toughness** A property of a material capable of absorbing energy by plastic deformation (see fracture toughness).

**Young's modulus** The ratio of a simple tensile stress applied to material to the resultant strain parallel to the tension.

## Abbreviations

**ASTM** American Society for Testing and Materials

**BCC** Body-centered cubic

**HCP** Hexagonal close-packed

**HIC** Hydrogen-induced cracking

**MIC** Microbiologically-influenced corrosion

**ppm** Parts per million (by weight)

**SCC** Stress corrosion cracking

**SCE** Saturated calomel electrode

**UNS No.** Unified Numbering System number

## Symbols

**H<sub>c</sub>** Critical hydrogen concentration for hydrogen-induced cracking [ppm]

**pH**  $-\log$  (hydrogen ion activity)

**pK<sub>a</sub>**  $-\log$  (acid dissociation constant)

**Ti<sub>x</sub>Fe** Intermetallic compound of titanium and iron with uncertain stoichiometry represented by *x*

**TiH<sub>x</sub>** Titanium hydride with uncertain stoichiometry represented by *x*

**α** The hexagonal phase of titanium

**β** The cubic phase of titanium

### 3.10.1 Introduction

The key attributes of titanium and its alloys are high strength-to-density ratios and corrosion resistance, making these materials attractive choices for aerospace applications and the chemical process industry, respectively.<sup>1–6</sup> More recently, improvements in the corrosion resistance of the higher strength alloys by minor alloying additions have led to their expanded usage as medical and dental implants.<sup>7</sup>

### 3.10.2 General Physical Properties

Titanium has two elemental crystalline structures, the hexagonal close-packed (HCP)  $\alpha$  structure and the body-centered cubic (BCC)  $\beta$  structure.<sup>8–11</sup> While commercially pure Ti has the  $\alpha$  structure, the impurity Fe and added alloying elements can produce a range of alloy microstructures. Depending on the predominant phase, Ti and its alloys are classified as  $\alpha$ , near- $\alpha$ ,  $\alpha$ - $\beta$ , or  $\beta$ .<sup>9</sup> The commercially

pure materials have the  $\alpha$  structure and vary in oxygen content depending on strength requirements. The already good corrosion resistance of these materials can be further improved by the addition of small amounts of Pd and Ru.<sup>7</sup> The near- $\alpha$  alloys retain the HCP structure, but the addition of metals such as Al, Sn, V, Mo, and Ni may stabilize small amounts of the  $\beta$ -phase. This leads to increases in strength and toughness. The addition of very small amounts (<1 wt%) of Mo and Ni, and especially Pd or Ru, improves their corrosion resistance. Further increases in alloy content, particularly V and Al, lead to a range of higher strength  $\alpha$ - $\beta$  alloys, whose corrosion resistance can again be enhanced by Pd or Ru additions. The  $\beta$  alloys, predominantly used in aerospace applications, contain additional alloying elements, such as Cr, Zr, and Nb.

When corrosion resistance is paramount,  $\alpha$  or near- $\alpha$  alloys are the appropriate choice, while  $\alpha$ - $\beta$  and  $\beta$  alloys are more appropriately selected for high-strength applications. Table 1 shows a representative selection of materials and properties. More extensive listings and a general description of mechanical properties are available elsewhere.<sup>2,5-7</sup>

Small variations in impurity Fe content (generally <0.2 wt%) and distribution influence the microstructure by inhibiting grain growth during fabrication. This leads to decreased  $\alpha$ -grain size and Fe-stabilized  $\beta$ -phase along grain boundaries. Fe contents ( $\geq 0.03$  wt%) can lead to the precipitation of  $\text{Ti}_x\text{Fe}$  particles on grain boundaries and at triple points.<sup>12-14</sup> The time spent in the temperature range 700–860 °C (during fabrication, welding, or heat treatments) enhances  $\beta$ -phase and  $\text{Ti}_x\text{Fe}$  formation.

Small microstructural changes also occur on addition of the slightly soluble Pt group metals.<sup>7</sup> Pd can form intermetallic compounds in the  $\alpha$ -matrix without affecting grain growth, while Ru additions stabilize  $\beta$ -phase and inhibit  $\alpha$  grain growth. For near- $\alpha$  Ti containing 0.15 wt% of Ru,  $\beta$ -phase Ru content can exceed 10 wt%.<sup>15</sup> In  $\alpha$ - $\beta$  alloys, both Pd and Ru are accommodated in the  $\beta$ -phase and the microstructure is unaffected.<sup>7</sup> Since both noble metals and Fe stabilize  $\beta$ -phase and intermetallics, their cosegregation can occur. For example,  $\beta$ -phase containing 12 wt% Ru and 5 wt% Fe is observed in Ti containing 0.15 wt% Ru,<sup>16</sup> and grain boundary phases containing 2.6–6.9 wt% Fe and 0.3–0.8 wt% Pd are observed in Grade-7 (0.15 wt% Pd).<sup>16</sup>

### 3.10.3 General Corrosion Properties

Titanium is highly reactive with oxygen, and its corrosion resistance is attributable to the presence of a chemically inert, adherent, oxide film. This film forms spontaneously in air and aqueous environments and can be amorphous or crystalline, depending on the mode and rate of formation, slow growth favoring crystallinity.<sup>17-19</sup> The crystalline oxide can be anatase or the more stable rutile.<sup>20-22</sup> The presence of oxygen vacancies and  $\text{Ti}^{\text{III}}$  interstitial ions makes the oxide an n-type semiconductor.<sup>23-25</sup> Its composition is close to  $\text{Ti}^{\text{IV}}\text{O}_2$  with  $\text{Ti}^{\text{III}}/\text{Ti}^{\text{II}}$  states at the metal-oxide interface.<sup>26,27</sup> The oxide-solution interface is commonly hydrated.<sup>20</sup>

For  $\alpha$  and near- $\alpha$  alloys, alloying elements (Pd, Ru, Ni) do not incorporate into the oxide, but, for  $\alpha$ - $\beta$

**Table 1** Composition and properties of selected ASTM grades of titanium

ASTM grade (UNS No.)	Alloy type	Nominal composition (wt%)	Minimum yield strength (MPa)	Minimum tensile strength (MPa)
1	$\alpha$	0.06 O	170	240
2	$\alpha$	0.12 O	275	345
4	$\alpha$	0.3 O	483	550
7	$\alpha$	0.12 O, 0.15 Pd	275	345
16	$\alpha$	0.12 O, 0.05 Pd	275	345
26	$\alpha$	0.12 O, 0.1 Ru	275	345
9	Near- $\alpha$	3 Al, 2.5 V	483	620
18	Near- $\alpha$	3 Al, 2.5 V, 0.05 Pd	483	620
12	Near- $\alpha$	0.3 Mo, 0.8 Ni	345	483
28	Near- $\alpha$	3 Al, 2.5 V, 0.1 Ru	483	620
5	$\alpha$ - $\beta$	6 Al, 4 V	828	895
24	$\alpha$ - $\beta$	6 Al, 4 V, 0.05 Pd	828	895
25	$\alpha$ - $\beta$	6 Al, 4 V, 0.5 Ni, 0.05 Pd	828	895
19	$\beta$	3 Al, 8 V, 6 Cr, 4 Zr, 4 Mo	759	793
20	$\beta$	3 Al, 8 V, 6 Cr, 4 Mo, 4 Zr, 0.05 Pd	759	793

alloys the oxide on the  $\beta$ -phase is slightly enriched in Al and V.<sup>28,29</sup> The oxide thickness and crystallinity may vary spatially.<sup>30</sup> The film at grain boundaries may be less protective than that on the grains when secondary phases are present.<sup>16,31</sup> The durability of this film is essential for corrosion protection, and the parameters most likely to influence its properties are (i) environmental redox conditions (i.e., corrosion potential), (ii) pH, and (iii) temperature.

### 3.10.3.1 Influence of pH

For  $\text{pH} < 4$ , the oxide can dissolve<sup>31</sup> and the Ti become active. An active to passive transition is observed over the potential range  $-0.7$  to  $-0.3$  V (vs. SCE).<sup>32</sup> Active corrosion can be rapid, leading to surface hydride ( $\text{TiH}_x$ ) formation,<sup>2</sup> but the rate is significantly suppressed on Pd- and Ru-containing alloys,<sup>7</sup> which become surface-enriched in Pd/Ru.<sup>33–38</sup> Even for hot, strongly reducing acidic conditions, enrichment can catalyze proton reduction and shift the corrosion potential into the passive region; this process is known as cathodic modification,<sup>39,40</sup> and is also observed with the Grade-12 alloy.<sup>41</sup>

In a sufficiently oxidizing environment, the corrosion potential will be  $> -0.3$  V (vs. SCE) and the alloy passive. Corrosion rates are negligible and insensitive to environment and to temperature well above  $100^\circ\text{C}$ .<sup>2,5</sup> An increase in potential thickens the oxide and makes it less defective.<sup>42</sup> For an applied potential  $> 1$  V (vs. SCE), a current for water oxidation to  $\text{O}_2$  is observed,<sup>43,44</sup> and often mistaken for the onset of pitting in  $\alpha$  and near- $\alpha$  alloys. Pitting only occurs in  $\text{Br}^-$  solutions, an effect which has been attributed to  $\text{Br}^-$  adsorption at sites associated with impurity inclusions containing either Al and Si or Fe.<sup>50–52</sup> In  $\text{Cl}^-$  solutions, polarization to  $> 5$  V (vs. SCE) is required to induce pitting,<sup>53,54</sup> and temperatures  $> 100^\circ\text{C}$  are required before pitting potentials decrease to  $\sim 2$  V (vs. SCE). Pitting requires high film stresses leading to film breakdown/recrystallization and the introduction of enhanced transport pathways for  $\text{Cl}^-$  ions.<sup>44,55–57</sup>

Since potentials  $> 1$  V (vs. SCE) are unattainable under natural corrosion conditions, pitting does not occur in Ti and its alloys, and protection against active corrosion is ensured at corrosion potentials  $> -0.3$  V (vs. SCE). Protection can be ensured by anodic protection<sup>58–60</sup> or by the addition of small concentrations of oxidants (e.g.,  $\text{O}_2$ ,  $\text{Fe}^{3+}$ ).<sup>2,5</sup> Anodic or thermal oxidations are also options,<sup>61,62</sup> but anodic oxidation produces only short term protection.

In dry environments (e.g.,  $\text{Cl}_2$  gas) and organic process streams, only small amounts of moisture or  $\text{O}_2$  are needed to maintain passivity.<sup>2,63</sup>

Corrosion rates increase in alkaline solutions as the protective oxide is more soluble, but, except at high temperatures, they remain low.<sup>2,5,64</sup> In peroxide solutions at  $\text{pH} > 12$ , commonly encountered in the pulp and paper industry, corrosion rates can be extremely high.<sup>65,66</sup> These high rates are attributed to the aggressive  $\text{HO}_2^-$  anion, the dominant form of peroxide above  $\text{pH} 10.6$  (the  $\text{pK}_a$  for  $\text{H}_2\text{O}_2$ ).<sup>67–69</sup> By contrast, peroxide, while modifying the passive oxide, does not cause rapid corrosion at lower pH values.<sup>70,71</sup>

### 3.10.3.2 Influence of Temperature

For active conditions (reducing acids and alkaline peroxide), increasing the temperature increases corrosion rates, but its influence under passive conditions is marginal. As the temperature is increased up to  $\sim 70^\circ\text{C}$ , the passive film becomes more crystalline and absorbs water,<sup>17,72,73</sup> and flaws begin to appear.<sup>57,74</sup> Although observable through the fluctuations in corrosion potential that they cause, these flaws rapidly self-repair and no significant loss of passivity is observed up to  $150^\circ\text{C}$  in  $\text{Cl}^-$  solutions.<sup>75,76</sup> In fact, extensive corrosion testing in extremely saline environments to temperatures well above  $200^\circ\text{C}$  shows that corrosion rates are not significantly enhanced.<sup>39,77–84</sup>

### 3.10.3.3 Influence of Fluoride

Fluoride appears to be the only ion in aqueous solution that is able to destroy passivity. Its influence has been studied widely for dental applications,<sup>85–101</sup> since dental gels and rinses can contain  $1000$ – $10\,000\ \mu\text{g g}^{-1}$  (ppm) of  $\text{F}^-$  in the pH range 3.5 to neutral, and in flue gas scrubber environments,<sup>102,103</sup> in which the liquors formed can contain up to  $\sim 1000\ \text{mg l}^{-1}$  of  $\text{F}^-$ . This aggressiveness is attributed to the solubilization of Ti as  $\text{TiF}_6^{2-}$  and  $\text{TiF}_6^{3-}$  aqueous complexes. It is generally recognized that a substantial  $\text{F}^-$  concentration and a low pH must coexist<sup>104,105</sup> for passivity to be lost. The pH threshold varies with  $\text{F}^-$  concentration and the Pd/Ru content of the alloy; for example, for a Pd content  $> 0.1\ \text{wt}\%$ , passivity in  $900\ \text{mg l}^{-1}$  of  $\text{F}^-$  is maintained at pH 4, while at  $9000\ \text{mg l}^{-1}$  no general corrosion was observed at pH 6.5 but shallow (up to  $\sim 2\ \mu\text{m}$  in cross section) pitting was observed.<sup>98</sup> The most likely location of these pits is at Fe impurity sites in grain boundaries. Their extensive propagation is unlikely because it will be limited by the cathodic modification process.<sup>98–101</sup>

Despite the much more aggressive environments, the influence of  $F^-$  in flue gas scrubbers is muted. These environments contain  $Cl^-$  up to  $15\,700\,\mu g\,g^{-1}$ ,  $SO_4^{2-}$  in the range  $9000\text{--}26\,000\,\mu g\,g^{-1}$ ,  $F^-$  up to  $12\,000\,\mu g\,g^{-1}$ , and the pH can be as low as 1 (at  $T \sim 170\text{--}180\,^{\circ}C$ ).<sup>102,103</sup> For Ti Grades-2 and-12,  $F^-$  led to a loss of passivity for  $pH \leq 3$  and  $<1.5$ , respectively. The relatively minor influence of  $F^-$  was attributed to its removal by complexation with cations (e.g.,  $NaF$ ,  $Na_2F^+$ ,  $CaF^+$ ) and its reaction with the silica in fly ash. The resilience of Pd/Ru-containing alloys in extreme environments has been demonstrated by testing of the Ti-6Al-4V-Ru alloy (Grade-29) in deep gas well environments.<sup>106</sup>

### 3.10.3.4 Hydrogen Absorption into Ti

Under active conditions (reducing acid and alkaline peroxide solutions) corrosion is driven by  $H^+$  reduction leading to H absorption.<sup>24</sup> Since the solubility of H in  $\alpha$ -Ti is low ( $20\text{--}100\,\mu g\,g^{-1}$  at room temperature, depending on alloy composition<sup>107</sup>), brittle hydrides then precipitate in  $\alpha$ - and near- $\alpha$  alloys, and embrittlement may be possible. Also, even relatively small H contents ( $>70\,\mu g\,g^{-1}$ ) can cause a loss of impact toughness.<sup>108</sup> However, at room temperature, the diffusion coefficient of H in the  $\alpha$ -phase is low,<sup>109,110</sup> and H is retained in a surface hydride layer<sup>2,5,111–113</sup> and material integrity is not challenged.

The rate and extent of absorption depend on alloy composition, microstructure, and temperature. On Pd/Ru alloys, catalysis of  $H^+$  reduction leads to enhanced absorption,<sup>40,114</sup> but this can be limited by solution aeration.<sup>115</sup> In the Grade-12 alloy,  $Ti_2Ni$  particles act as galvanically-coupled cathodes in the  $\alpha$ -matrix and form hydride readily.<sup>116</sup> Furthermore, the Ni-stabilized  $\beta$ -phase in the grain boundaries facilitates H transport into the bulk of the alloy, as the  $\beta$ -phase diffusion coefficient is  $\sim 10^5$  times that in the  $\alpha$ -phase.<sup>110,117</sup>

The passive oxide is generally impermeable to H, and the absorption efficiency approaches zero for  $pH > 3$ ,<sup>118</sup> unless the alloy is cathodically polarized to  $<-0.6\,V$  (vs. SCE) when redox transformations in the oxide are accompanied by H absorption ( $TiO_2 + H^+ + e^- \rightarrow TiOOH$ ).<sup>119–124</sup> Although the oxide is then rendered permeable, significant H transport through it requires a potential  $<-1.0\,V$  (vs. SCE).<sup>119,125</sup>

Polarization to these potentials requires either galvanic coupling to active metals (e.g., Zn or carbon steel) or the application of cathodic protection. To avoid significant hydrogen absorption, an operating

threshold of  $>-0.7\,V$  (vs. SCE) is recommended.<sup>2</sup> Although the potentials during galvanic coupling to carbon steel can be below this value (at temperatures in the range  $18\text{--}60\,^{\circ}C$ <sup>126</sup>), the H absorption rate (generally measured at  $-1.0\,V$  (vs. SCE)) decreases parabolically with time as H accumulates in a surface hydride layer<sup>127,128</sup> and absorption becomes controlled by diffusion into the alloy. For  $\alpha$ -alloys, the transport is slow and little damage is done. For Grade-12 Ti, however,  $\beta$ -phase transport accelerates diffusion and the overall absorption rate is higher.<sup>129</sup> Since diffusion coefficients are temperature-dependent, embrittlement below  $80\,^{\circ}C$  is not expected.<sup>2</sup> Generally, this is observed to be the case,<sup>130</sup> although high stress levels promote absorption and hydriding.<sup>131</sup>

Cathodic protection is common in marine applications, with relative absorption tendencies in the order  $Ti-12 > Ti-2 > Ti-5/Ti-9$ .<sup>132</sup> Noble metal additions to near- $\alpha$  and  $\alpha$ - $\beta$  alloys increase absorption only slightly (up to  $\sim 40\%$ ).<sup>128</sup> Thermal oxidation prior to exposure suppresses absorption (in 6% NaCl, up to  $120\,^{\circ}C$ ),<sup>135</sup> and H absorption in deaerated HCl ( $2 \leq pH \leq 4$ ) up to  $250\,^{\circ}C$  can be prevented by aeration.<sup>115</sup>

## 3.10.4 Localized Corrosion Processes

A major asset of Ti alloys is their apparent immunity to many localized corrosion processes, especially pitting and vapor phase corrosion<sup>2,5,134,135</sup> and microbially-influenced corrosion (MIC).<sup>134–143</sup> The two predominant localized corrosion failure modes are crevice corrosion and hydrogen-induced cracking (HIC).

### 3.10.4.1 Crevice Corrosion

Crevice corrosion is generally observed in hot oxidizing halide (or, less commonly, sulfate) environments, under tight gaskets, in metal-metal joints, and under adherent deposits produced in industrial process streams. Reviews summarizing industrial observations and laboratory studies have been published.<sup>2,5,144</sup> For the most commonly used Ti material, Grade-2, it is accepted that crevice corrosion will not occur for  $T < 70\,^{\circ}C$ , regardless of pH and  $Cl^-$  concentration, and for  $pH > 10$ , regardless of temperature.

The initiation of crevice corrosion requires a loss of passivity and the establishment of active corrosion

conditions within the creviced region. The importance of temperature shows that initiation is primarily dependent on the film breakdown events, which commence around 70 °C.<sup>57,74–76</sup> The rapid repair observed on open surfaces does not occur within a tight crevice, and the acidity developed by dissolved metal cation ( $\text{Ti}^{3+}/\text{Ti}^{4+}$ ) hydrolysis leads to the establishment of active conditions.<sup>145</sup> Once initiated, propagation is rapid and extensive, being supported both within the crevice by  $\text{H}^+$  reduction (70–80%) and outside the crevice by  $\text{O}_2$  reduction (30–20%).<sup>12,146</sup>

For Grade-2 Ti, the depth of crevice penetration is dependent on the amount and distribution of the impurity Fe. When Fe is present in grain boundaries, but not separated into  $\text{Ti}_x\text{Fe}$  precipitates, penetration (at 95 °C) is rapid (up to 2 mm) and limited only by the ohmic potential drop caused by corrosion product accumulated within the crevice.<sup>147</sup> When  $\text{Ti}_x\text{Fe}$  precipitates are present, the crevice is polarized to repassivation (by the cathodic modification mechanism), and penetration is limited to  $\leq 0.8$  mm.<sup>12,119</sup> For Grade-12, which contains a large number of  $\text{Ti}_2\text{Ni}$  precipitates, repassivation occurs more rapidly, and penetration is limited to  $< 0.4$  mm.<sup>148</sup> The inherent instability of this alloy is clear from the observation that  $> 95\%$  of the damage is due to proton reduction within the creviced site.<sup>148</sup>

The threat of crevice corrosion can be effectively eliminated by alloying Ti with Pd or Ru.<sup>7</sup> Despite the presence of film fracture events for  $T > 70$  °C,<sup>12</sup> no significant damage occurs up to 200 °C on near- $\alpha$  and  $\alpha$ - $\beta$  alloys, even in extremely aggressive environments such as 10%  $\text{FeCl}_3$  (pH 2) and  $\text{Cl}_2$ -saturated 20% NaCl.<sup>81</sup> Other methods of preventing, mitigating, or at least detecting, crevice corrosion have been discussed.<sup>5,149,150</sup>

### 3.10.4.2 Environmentally-Assisted Cracking

The primary factors influencing these processes, which include stress corrosion cracking (SCC), corrosion fatigue cracking, and HIC have recently been reviewed.<sup>5</sup> These processes can often occur simultaneously, and a case can be made that H absorption is a key feature of crack propagation in all three processes.

#### 3.10.4.2.1 Stress corrosion cracking

Since passivity is difficult to breach, the majority of Ti alloys do not suffer SCC except in aqueous halide

systems and in a few nonaqueous environments, such as dry methanol, where the addition of even small amounts of water is enough to ensure passivity and avoid cracking.<sup>5</sup> In aqueous halides, SCC is more likely at high concentrations, low pH, and high temperature, and appears to progress via oxide rupture and local acidification leading to H absorption and crack tip embrittlement.<sup>151,152</sup>

The ductility and passivity of Ti alloys means industrial failures are unusual and generally observed only for higher strength near- $\alpha$  alloys containing Al and Sn. When SCC is feared, susceptibility can be reduced by using alloys with low interstitial ion (O, C, N) contents. Generally, initiation requires the presence of stressed surface cracks or flaws. Recently, extensive testing of Grades-12 and -7 over a 4 year period in a range of saline environments (pH 2.7 to  $> 12$ ; 60–90 °C) confirmed the resistance of these materials to SCC,<sup>153</sup> although cracking could be forced to occur when low-frequency cyclic loading was applied.<sup>154</sup>

#### 3.10.4.2.2 Hydrogen-induced cracking

For HIC to occur, a considerable amount of H must be absorbed by the alloy, which is most likely to occur when cathodic protection is applied. The tolerance of an alloy for H will be a function of H solubility, and the material's microstructure and texture. The solubility of H is very different in the  $\alpha$  and  $\beta$  phases (20–100 and  $> 9000$   $\mu\text{g g}^{-1}$ , respectively), making  $\beta$ -alloys generally insensitive to HIC. However, this difference, and the more rapid transport of H through the  $\beta$ -phase than through the  $\alpha$ -phase, mean that the microstructure of near- $\alpha$  and  $\alpha$ - $\beta$  alloys has a strong influence on HIC.

Even H contents as low as 70  $\mu\text{g g}^{-1}$  can lead to a decrease in impact toughness,<sup>5,155</sup> although the resistance can be improved by increasing the Al content of the alloy.<sup>5</sup> However, under slow straining or sustained load conditions, tolerance for H is much higher. Slow strain rate tests on Ti Grades-2 and -12 indicate no influence on fracture toughness below a critical level ( $H_c$ ),<sup>156–158</sup> which is taken to be the concentration below which fast crack growth will not occur. The combinations of stress intensity factor and H concentration leading to either fast crack growth (brittle failure) or slow crack growth by either sustained load cracking or ductile rupture, or to no failure have been determined.<sup>156–158</sup>

The values of  $H_c$  were found to be very sensitive to material microstructure and texture with respect to the orientation of the crack and the applied stress.<sup>159</sup>

For Grade-2 Ti, depending on crack orientation with respect to the laminations introduced by rolling,  $H_c$  varied between  $\sim 400$  and  $1000 \mu\text{g g}^{-1}$ .<sup>157</sup> For Ti Grade-12,  $H_c$  for cracks aligned with the rolling direction was  $500 \mu\text{g g}^{-1}$  compared with  $2000 \mu\text{g g}^{-1}$  for cracks perpendicular to this direction. Values of  $H_c$  rose markedly with temperature, which was attributed to the prevention of stress concentration by enhanced creep deformation.<sup>157</sup> Similar measurements for the Grade-5  $\alpha$ - $\beta$  alloy yielded  $H_c = 200 \mu\text{g g}^{-1}$ .<sup>159</sup> On the basis of these measurements, models to predict HIC failures of Ti nuclear waste containers have been developed.<sup>160–163</sup>

### 3.10.5 Specific Applications

Because titanium is an expensive material, its practical use is limited to applications that require one or both of the material's particular performance advantages: superior corrosion resistance and high strength-to-density ratio. Alloying to improve these properties adds further expense. As a commercial material, Ti and its alloys have an established history of reliable long term performance in aggressive environments, including hot oxidizing acids, hot saline solutions, chlorine- and sulfur-bearing gases, and organic solvents. Its industrial and commercial usage continues to grow, and Ti is now the material of choice for many chemical, marine, biomedical, and energy systems applications. Two recent extensive reviews are available.<sup>164,165</sup>

#### 3.10.5.1 Aerospace

The emergence of Ti as an industrial material in the late 1940s and 1950s was driven primarily by the demands of military, and subsequently commercial, aircraft production. While corrosion resistance is important, the primary reasons to use Ti in aircraft and spacecraft are its high strength-to-density ratio and high temperature performance.<sup>165,166</sup> While maintaining the strength of steel, Ti is 45% lighter, and is twice as strong as Al, but only 60% heavier.<sup>164</sup> Ti is an effective replacement for Al alloys for temperatures above  $130^\circ\text{C}$ , the normal limit for conventional Al. The right choice of alloy permits Ti engine components to function at temperatures up to  $600^\circ\text{C}$ .<sup>166</sup>

The main, general-purpose aerospace alloy is Grade-5, although many others are adopted for specific situations. Ti comprises  $\sim 10 \text{ wt}\%$  of the airframe of a modern commercial aircraft<sup>167</sup> and up

to 95 wt% in military planes. Gas turbine engines have  $\sim 30 \text{ wt}\%$  Ti.<sup>165</sup> Ti bands are even wrapped around Al fuselages to prevent propagation of fatigue cracks.<sup>165</sup>

Except for hot hydraulic fluids, few media encountered in the aerospace environment can corrode Ti, allowing the use of unpainted/uncoated Ti throughout the aircraft. Paint is only necessary at Ti interfaces with Al or low-alloy steels to prevent galvanic corrosion.<sup>166</sup> The use of Ti alloys is mandated for lavatory and galley floors because of the corrosiveness of those environments to Al and steels.<sup>165,166</sup> Even the hydraulic fluid problem, in which organophosphoric acids produced by high temperature breakdown can cause severe etching of Ti alloys and H absorption to embrittlement, has been managed using the  $\beta$ -alloy Timetal 215. This alloy is immune to attack by hydraulic fluid, purportedly through the synergistic effects of its Nb and Mo contents.<sup>166</sup>

#### 3.10.5.2 Seawater and Brine

Ti alloys have supplanted cupronickel alloys, such as Monel, as the preferred materials for heat exchangers and condensers in brackish water, seawater, and polluted waters. Unlike the cupronickel alloys, Ti is immune to general corrosion up to  $260^\circ\text{C}$ , and resistant to localized corrosion processes, sulfide attack, and flow-accelerated forms of corrosion. Flow rates over  $36 \text{ m s}^{-1}$  do not cause erosion corrosion, cavitation corrosion, or impingement attack in the presence of abrasive particles such as sand.<sup>164,165,168</sup> This allows the use of thin-walled tubing (with good heat transfer properties), as a zero corrosion allowance can be specified. This reliability is demonstrated by the industrial use of millions of meters of tubing over many decades without corrosion failures.<sup>164,165,168</sup>

Other seawater and brine applications include submarine hulls, surface ships, oil and gas platforms, desalination and salt production evaporators, and water jet propulsion systems.<sup>165,166,168</sup> Wet-dry cycling, water line exposure, and salt spray have no effect on corrosion.<sup>167</sup> Since Ti does not suffer MIC, it can withstand biofouling. It is not biotoxic, nor does it suffer corrosion in the presence of biocides.<sup>136,164,165,168</sup> Although it may require the specification of Pd/Ru-containing alloys, crevice corrosion can be avoided. As discussed earlier, galvanic corrosion can be an issue for Ti in seawater environments. Since Ti is normally the cathode in the galvanic couple, it can accelerate attack of the active anodic material while absorbing H itself. While

embrittlement and HIC are not issues at low temperatures, they can be at higher temperatures (Sections 3.10.3.4 and 3.10.4.2.2).

### 3.10.5.3 Biomedical and Dental Implants

The oxygenated, warm (37 °C), neutral (pH ~ 7.4) saline conditions encountered in the human body are not aggressive towards Ti. Its corrosion resistance, including resistance towards processes involving stress and fatigue, and biocompatibility make Ti an ideal implant material.<sup>169</sup> Its major uses include cranial plates, orthopedic fracture plates, joint replacements, stents, catheters, pacemaker cases, dental implants and wires, and maxillofacial and orbit reconstruction plates.<sup>170</sup> The extremely low corrosion rates mean Ti dental implants have no taste.<sup>164</sup>

Nitinol shape-memory materials, often used in orthodontics and stents, have been known to undergo pitting and crevice corrosion *in vivo* if heat treatments leave a crystalline oxide on the surface. However, this can be avoided by applying surface treatments to produce an amorphous oxide.<sup>171</sup> Corrosion fatigue, though rare, has been observed on Ti-6Al-4V implants.<sup>172</sup> Some cases of metallosis involving this alloy have also been encountered, but these are primarily due to fretting and wear producing fine metal particulates, rather than to corrosion.<sup>173,174</sup> Care must also be taken to avoid galvanic corrosion, even between materials as similar as commercially pure Ti and Ti-6Al-4V implants.<sup>170</sup>

Although Ti alloys are corrosion resistant *in vivo*, and there have been no clinically substantiated reports of problems stemming from the presence of Al and V in the implants,<sup>174</sup> some concern over the long term impact of these alloying elements remains.<sup>174</sup> Studies on alternative materials to Ti-6Al-4V to avoid potentially toxic alloying compounds are underway.<sup>174-178</sup> In these new materials, V and Al are being replaced by various amounts of other less toxic elements, including Fe, Zr, Mo, Ta, and Sn. These materials possess similar corrosion properties to Ti-6Al-4V but have improved mechanical properties, such as a decreased Young's modulus.

### 3.10.5.4 Chemical Processing and Power Generation

The use of Ti and its alloys in the chemical process industry has been extensively reviewed<sup>2,5</sup> and will not be dealt with here, except to note that their usage is still expanding. The key corrosion issues, as

discussed earlier, are crevice corrosion and hydrogen absorption leading to embrittlement and cracking.

Titanium alloys have recently been extensively studied as candidate materials for the fabrication of high-level nuclear waste containers and container dripshields.<sup>134,135,153,160,179,180</sup> The critical requirement in these applications is the need to maintain corrosion resistance over tens of thousands of years. The ability of Ti alloys to maintain extremely low corrosion rates over extensive time periods and their lack of susceptibility to localized corrosion processes<sup>135,160</sup> make them ideal candidates for this application. A particularly attractive feature is their insensitivity to  $\gamma$ -radiation even at extremely high dose rates.<sup>181</sup>

### 3.11.1 Introduction

#### 3.11.1.1 History and Production

Lead was one of the metals known in antiquity; there is evidence of lead production dating back to before the early Bronze Age, with a lead figurine from Upper Egypt dated to approximately 3000 BC.<sup>1</sup> However, at that time lead does not appear to have been greatly prized as it is soft and easily tarnishes. Indeed, early lead ores seem to have been smelted mainly in order

to obtain the silver, with which it frequently occurs. However, lead production grew very significantly during the Roman period, where it was useful in its own right for a number of purposes, including plumbing (water transport, water tanks, etc.) and kitchenware and drinking vessels (despite the knowledge, even in antiquity, that lead is generally harmful to human health).

Lead ores comprise mainly sulfide mineralization with smaller amounts of carbonate and sulfate.

Historically, lead was mined on its own (in the United Kingdom, Derbyshire and Leadhills in Southern Scotland were historic sources). Modern ores frequently occur along with zinc, and other species (silver, copper, gold, antimony, bismuth, etc.) in considerably lesser amounts. Lead sulfide (galena) is easily smelted by roasting in air to produce lead oxide, then by carbothermic reduction, which traditionally used charcoal but now uses coke, in a blast furnace.

Lead is currently produced in Australia, China, the United States, Canada, Mexico, and Peru. Western Europe produces about 8% of the total world ore production of around 3 million tonnes (2007), mainly from Sweden, but also Ireland and Spain. Lead is amongst the most recyclable of all metals and has by far the highest recycling rate, primarily from batteries and also from usage in the building trade. Secondary (i.e., recycled) sources of lead generally account, in developed economies, for more than 70% of lead usage.

### 3.11.1.2 Physical Properties

Lead is characterized by its relatively high density (in comparison to other engineering materials), its extremely low hardness and strength, and its favorable electrochemical properties, including its good resistance to corrosion.<sup>1,2</sup> However, it should be noted that lead is by no means the most dense element; for example, tungsten and tantalum are significantly more dense. **Table 1** provides a summary of some physical properties in comparison with other materials.

The density of lead provides it with useful properties in respect of the attenuation of phonon vibrations and electromagnetic waves. Thus, the mass attenuation coefficient for lead is relatively high, and also the neutron absorption cross-section for lead is small, which makes lead effective for the radiation shielding

of X-rays,  $\gamma$ -rays, and neutrons. In addition, the softness and high mass of lead effectively damps the propagation of sound waves.

### 3.11.1.3 Applications

Traditionally, lead as a metal has a number of uses driven by its general resistance to corrosion, as well as its electrochemical properties in rechargeable lead–acid batteries. The main uses of metallic lead are<sup>2</sup>

1. *Lead–acid batteries*: this currently accounts for over 50% and up to 90% of use in certain countries; most lead used in this way is recovered and recycled into the secondary lead market.
2. *Construction*: the main application in construction is for waterproofing flashings and roofing of historic buildings, as well as architectural detailing; the traditional use in water pipes and water storage has now vanished; lead from construction also has a high recycling rate.
3. *Chemical industry*: lead lining of vessels was traditionally used in the chemical industry, particularly in the production of sulfuric acid; however, these uses have now almost vanished.
4. *Metal joining*: lead is (with tin) a key component of solder used to join copper (piping, heat exchangers, etc.) and steels, and for electrical contacts; however, lead-free solders are now widely used in the water and electronics industry.
5. *Munitions*: lead is traditionally used in the manufacture of ammunition, although depleted uranium and tungsten, which are both significantly more dense than lead, are used in high performance (e.g., armor piercing) rounds; however for sporting purposes nontoxic alternatives exist and are increasingly being used.
6. *Dense metals*: lead is used for radiation shielding, for sound dampening, and for balancing of machinery; weights used in sporting applications

**Table 1** Physical properties of lead compared with some other common metals

	<i>Pb</i>	<i>Sn</i>	<i>W</i>	<i>Cu</i>	<i>Fe</i>
Atomic number	82	50	74	29	26
Atomic weight (g)	207.19	118.69	183.84	63.55	55.85
Density (g cm <sup>−3</sup> )	11.34	7.3	19.3	8.96	7.87
UTS, 99.9% pure (MPa)	12–15	20–30	950–1000	120–170	100–200
Melting point (K)	601	505	3680	1358	1810
Boiling point (K)	2020	2540	5830	2816	3130
Electrical conductivity $\times 10^6$ ( $\Omega^{-1}$ cm <sup>−1</sup> )	0.048	0.079	0.189	0.596	0.099
Thermal conductivity (W cm <sup>−1</sup> K <sup>−1</sup> )	0.35	0.73	1.74	4.01	0.238
Linear expansion coefficient $\times 10^{-6}$	29.0	23.5	–	16.5	12.2
Crystal structure (room temperature)	fcc	bct	bcc	fcc	bcc

(such as fishing weights) are being phased out in favor of nontoxic alternatives.

7. *Cable sheathing*: the first electrical cables were sheathed with lead to protect the cable from moisture ingress. For undersea cables, especially high-voltage power transmission lines, there is still no adequate alternative; thus, properly applied lead sheathing has zero water and water vapor transmission.
8. *Alloying*: lead is used as an addition in a number of alloys, including solders, pewter, bearing alloys, etc.; it also may be added to other materials (such as copper alloys and steels) to improve machinability, although alternatives are now available.
9. *Anodes*: by virtue of its relative chemical stability and easy passivation, lead is used as an insoluble anode in many electroplating processes (e.g., for chromium); traditionally, it was also used as a nonconsumable anode in cathodic protection systems, but this application area is decreasing as alternatives now exist.
10. *Fusible alloys*: eutectic alloys containing lead with bismuth, tin, cadmium, and indium are used as low melting point fuses and plugs in certain applications such as sprinkler systems, etc.

### 3.11.1.4 Alloying

Apart from tin, indium, and bismuth, lead has extremely limited solid solubility for most elements at room temperature, although solubility can

increase somewhat at higher temperatures.<sup>3</sup> Thus, most lead alloys consist of primary lead grains either with second phase particles (which may be intermetallic compounds), or with a eutectic mixture, decorating the grain boundaries. Because of the very poor mechanical properties of high-purity lead, alloying is almost always essential in order to achieve acceptable performance. Most commercial lead alloys contain a few tenths of a percent of alloying elements, with strengthening caused by precipitation or by the presence of a eutectic; many alloys are age-hardenable. The main classes of alloy listed below with composition ranges presented in [Table 2](#):

1. *Lead–antimony (+ tin, arsenic)*: the traditional alloy used for batteries, ammunition, sheet, and chemical plant; still very widely used, but the battery application is increasingly being replaced with lead–calcium.
2. *Lead–calcium (+ tin, aluminum)*: increasingly replacing lead–antimony alloys, particularly in battery applications, as they have very low hydrogen evolution characteristics and can therefore be sealed. Lead–calcium–tin is used for electrowinning anodes.
3. *Lead–tin (+ silver, antimony)*: used for jointing alloys (solders) and bearings.
4. *Lead–copper*: used generally for sheet products and linings; also for cable sheathing and in chemical plant.
5. *Lead–silver*: used for anode materials and higher temperature solders.

**Table 2** Compositions of typical lead alloys

<i>Alloy type</i>	<i>Specification</i>	<i>Application</i>	<i>Composition</i>
Pb–Sb	BS EN 12548	Battery grids	1–3% Sb + 0.5–1% S, Se and Cu
		Ammunition	0.5–8% Sb + 0.02–3% As
		Cable sheaths	0.5–1% Sb
		Anodes	6–10% Sb + 0.5–1% As
	BS EN 12659	Chemical lead	<0.06% impurities
Pb–Ca	BS ISO 4381	Bearings	9–15% Sb + 1–20% Sn
		Battery grids	0.03–0.07% Ca; +0.03% Al and 0.3% Sn
		Cable sheath/splices	0.04% Ca
		Anodes	0.03–0.09% Ca; + up to 0.3% Sn
	BS EN ISO 9453	Solders	2–70% Sn; + up to 2% Sb
Pb–Sn	BS ISO 4999	Terne plate	15–20% Sn
Pb–Cu	BS EN 12588	Construction (sheet)	0.03–0.06% Cu
Pb–Ag		Battery grids	0.005–0.05% Ag
		Solder	1–6% Ag
		Anodes	0.25–2% Ag; + up to 1% Sn or up to 6% Sb
Pb–Te	BS 3909	Nuclear/radiation	0.06% Te
	BS EN 50307	Cable sheaths	0.035–0.1% Te; +0.03–0.08% Cu

6. *Lead–tellurium (+ copper)*: because of its low alloy content, used for radiation shielding and, with copper, is a cable sheathing alloy.

### 3.11.1.5 Mechanical Properties

#### 3.11.1.5.1 Lead

Unalloyed lead has relatively poor mechanical properties,<sup>2,4</sup> thus, in addition to a low ultimate tensile strength (<12 MPa), it has a very low yield stress (<4 MPa); these are considerably lower than tin, for example. The low melting point of lead means that, like tin, it undergoes recrystallization and grain growth at room temperature and is susceptible to creep at stresses above ~2 MPa (~15% of the UTS), which is very low indeed. Thus, while lead of purity in excess of 99.99% is commercially available (BS EN 12659), it is not specified unless its superior corrosion resistance is required. Lead is also susceptible to fatigue, particularly due to thermal cycling, and this is a key failure mechanism in pure and alloyed lead. Table 3 provides typical mechanical properties for pure lead as well as a range of common lead alloys.

#### 3.11.1.5.2 Lead alloys

Of the elements commonly found in lead alloys, zinc and bismuth aggravate corrosion in most circumstances, while additions of copper, tellurium, antimony, nickel, silver, tin, arsenic, and calcium affect corrosion resistance only slightly, or may even improve it depending on the service conditions. Alloying elements that are of increasing importance are calcium, especially in maintenance-free battery alloys and selenium or sulfur, together with copper as grain refiners (nucleants), in low antimony battery alloys. Other elements of interest are indium and silver in anodes,<sup>5</sup> aluminum in batteries (to control calcium losses),<sup>6</sup> and selenium in chemical lead as a grain refiner.<sup>7</sup>

In Europe, lead alloy designations are specified in ISO TR 7003, “Unified format for the designation of metals,” in the format PBnnnA. The designate ‘PB’ is the chemical symbol for lead, the three digits ‘nnn’ define specific alloy compositions, while the ‘A’ designates the application: ‘R’ for pure lead, ‘K’ for cable, ‘A’ for battery alloys, and ‘M’ for miscellaneous alloys.

Historically, lead for use in chemical plant was specified in BS 334, which defines compositions for five types of lead: A, B1, B2, B3, and C. This standard has now been superseded by BS EN 12659, “Lead and lead alloys,” which specifies the composition of effectively pure lead (formally type A). This is because satisfactory alternative materials exist such that lead is now rarely, if ever, specified in chemical plant. Type A lead should only be used in a vibration-free environment and where the superior corrosion resistance is of paramount importance. Historically, for general chemical plant use, type B1 (copper–lead) is to be preferred on account of its much greater structural stability, especially at elevated temperatures. Type B2 (copper–tellurium–lead) has extremely good fatigue resistance, which is retained to a greater extent at elevated temperatures, than does type B1. The main effect of tellurium is to form a fine-grained uniform grain structure, to enhance work hardening, and to delay recrystallization. The silver content in type B3 also delays recrystallization and promotes a large-grained stable structure, which is creep resistant. Type C (antimony–lead) is used for valves, pump bodies, and fatigue-resistant applications, but is not suitable for use at temperatures above 60 °C owing to a rapid increase in creep rate, or in sulfuric acid concentrations above 60%.

BS EN 12548, “Lead alloy ingots for electric cable sheathing and for sleeves,” gives compositional requirements for a range of lead alloys for this application.

**Table 3** Mechanical properties of selected lead and lead alloys

Material	Yield Stress (MPa)	UTS (MPa)	Elongation (%)	Fatigue limit (MPa)	Creep failure at 20 MPa (h)
99.99% Pb	3.5	12.2	55	2.7	–
0.06% Cu	9.0	17.5	55	4.9	–
0.06% Ca	24.3	27.9	30	9.0	10
0.5% Sn	27.9	41.8	15	–	30
0.08% Ca + 1% Sn	46.0	59.7	15	–	850
1% Sb	19.3	37.9	20	–	–
2% Sb	24.1	46.9	15	–	–
2.75% Sb	55.2	65.5	10	–	–
6% Sb	71.0	73.8	8	–	–

The main types are PB001K (formally type B), containing 0.85% antimony; PB021K (formally type E), containing 0.2% Sb and 0.4% Sn; and PB012K (formally 1/2C), containing 0.2% Sn and 0.07% Cd. Type B is suitable for use in environments where severe vibration is expected, while type E is relatively resistant to vibration compared with type 1/2C. The performance of these materials is generally adequate in underground or marine environments.

BS EN 12588, "Rolled sheet lead for building purposes," lays down requirements for composition, structure, thickness, freedom from defects, width and length, and marking. The specified copper content stabilizes the structure of the material, conferring resistance to thermal fatigue cracking caused by grain growth and thermal cycling.

Other UK, European, or worldwide specification standards exist for specific applications, for example, radiation shielding, soft solders, and bearing alloys. However, there are no standards for battery alloys as many of these are proprietary to specific battery manufacturers.

### 3.11.2 Electrochemistry

#### 3.11.2.1 Thermodynamics

Pourbaix *et al.*<sup>8</sup> studied the Pb–H<sub>2</sub>O and Pb–H<sub>2</sub>O–X systems, where X is a nonmetal, and have established

the domains of thermodynamic stability of lead, lead cations and anions, and insoluble compounds of lead. Figure 1 shows the Pb–H<sub>2</sub>O system in the absence of complexing agents such as acetic acid. Lead can be seen to be a relatively noble metal from pH > 5, but dissolves to form Pb<sup>2+</sup> species at lower pH and the plumbite oxyanion at pH > 10.5. This is due to the amphoteric nature of lead and is a significant factor in actual environments. Also, passivation at high potential, due to the formation of PbO<sub>2</sub>, is evident across the whole pH domain.

In regions where the dissolution of lead is possible, according to the thermodynamics, the rate of corrosion may be very slow. This is because the overpotential for hydrogen evolution on lead is very high in 1 M H<sub>2</sub>SO<sub>4</sub>, 10<sup>−12</sup> A cm<sup>−2</sup> with a Tafel slope of 0.125 mV per decade current, indicating that a 1-electron transfer reaction is rate controlling.<sup>9</sup> Corrosion in near-neutral environments generally results in passivation, with the development of insoluble salt film corrosion products. In strong alkali, the corrosion is more rapid with the formation of plumbite ions.<sup>10</sup> Consequently, in acidic or moderately alkaline solutions, free from complexing agents (particularly organic acids), the corrosion of lead is generally negligible.

In contrast with the Pb–H<sub>2</sub>O system, in the presence of significant concentration of sulfate ion, the

Figure 1 Pourbaix diagram for lead at a dissolved total metal ion concentration of 10<sup>−5</sup> M.

zone of thermodynamic stability of  $\text{PbSO}_4$  expands, and lead now passivates by the formation of a salt film of lead sulfate, which is the basis of lead's low corrosion rate in sulfuric acid (Figure 2).

In similar way, lead forms a series of relatively insoluble compounds, many of which are strongly adherent to the metal surface. Thus, in conditions where a stable continuous film can form, further reaction is often prevented or greatly reduced. The generally good corrosion resistance of lead results, therefore, from the formation of relatively thick protective films of corrosion product.

### 3.11.2.2 Dissolution

The standard electrode potential,  $E^0: \text{Pb}^{2+}/\text{Pb} = -0.126 \text{ V}$ ,<sup>11</sup> shows that lead is thermodynamically unstable in acid solutions, but stable in neutral solutions. In acid conditions, the exchange current density for the hydrogen evolution reaction on lead is very small ( $\sim 10^{-12} \text{ A cm}^{-2}$ ), but, at higher pH, control of corrosion is usually due to physical blocking of local anodes (from alloying additions and intermetallic compounds, which generally have higher exchange current densities) by virtue of insoluble lead salts that frequently form protective films. At  $\text{pH} > 11$ , lead will corrode freely at low anodic overpotentials dissolving

as the  $\text{HPbO}_2^-$  species. However, at higher potentials, it will passivate, again forming  $\text{PbO}_2$ . Lead may thus be used as an insoluble anode effectively throughout the entire pH range; an extremely useful characteristic. In summary, the corrosion rate of lead in an environment is frequently not controlled by the electrochemical processes but by the chemical dissolution rate of the corrosion product film.

Under strong cathodic polarization, disintegration can occur with lead, observable as a gray cloud of fine metal particles; this is a significant phenomenon in the application of lead to electrowinning (metal plating) anodes. Hydrogen evolved on the surface of the lead can be absorbed if the current density is sufficiently high,<sup>12</sup> and above this level, the formation of lead hydride may occur, which leads to severe disintegration.<sup>13</sup>

### 3.11.2.3 Oxidation and Passivation

Lead is characterized by a series of anodic corrosion products, which give a film or coating that effectively insulates the metal physically from the electrolyte, for example:  $\text{PbSO}_4$ ,  $\text{PbCl}_2$ ,  $\text{Pb}_3\text{O}_4$ ,  $\text{PbCrO}_4$ ,  $\text{PbO}$ ,  $\text{PbO}_2$ ,  $2\text{PbCO}_3 \cdot \text{Pb(OH)}_2$ ; of which  $\text{PbSO}_4$  and  $\text{PbO}_2$  are the most important, as they play a part in batteries and anodes. Lead carbonate and lead sulfate are

**Figure 2** Pourbaix diagram for lead-sulfur in 1 M sulfate ion concentration and a dissolved total metal ion concentration of  $10^{-5} \text{ M}$ .

particularly important also in atmospheric passivation and chemical industry applications.

In aqueous electrolytes, the anodic behavior of lead varies greatly, depending on the conditions prevailing. Extensive reviews of the aqueous electrochemistry of lead, including its anodic behavior, have been produced, for example, by Kuhn in 1979,<sup>14</sup> and much of this is still valid. The vast majority of historic and current research is concerned with the behavior of lead in sulfuric acid and this is understandable, given that the main application is still in lead-acid batteries. More recently, research has been concerned increasingly with environmental concerns, including lead removal from contaminated locations and the possible application of lead as a barrier material in nuclear waste disposal; these specific issues are dealt with in more detail later.

The dry oxidation of lead was studied in oxygen pressures from  $10^{-2}$  to 1000 torr and at temperatures between  $-90$  and  $150^{\circ}\text{C}$ .<sup>15</sup> Over several weeks, the oxide grew to a limiting thickness of about 10 nm. Ellipsometry and Auger electron spectroscopy confirmed that the oxide was PbO and that the growth law conformed to the Cabrera-Mott model (high-field ion conduction). X-ray diffraction data confirmed that the oxide was epitaxial to the lead, but that it was highly strained and that recrystallization of the lead substrate promoted oxide growth.

Passivation of lead in sulfuric acid is caused by the potential-dependent, and generally reversible, formation of PbO, PbSO<sub>4</sub>, and PbO<sub>2</sub>. However, the reactions and transformations are complex and difficult to characterize.<sup>16</sup> At potentials just above the reversible potential for lead oxidation, a dense layer of PbO can form together with porous PbSO<sub>4</sub>;<sup>17,18</sup> the growth of PbO formed in this way is controlled by the rate of oxygen anion transport through the oxide. At higher potentials, PbO and PbSO<sub>4</sub> transform to PbO<sub>2</sub>, which occurs in one of the two nonstoichiometric polymorphs, both with a slight oxygen deficiency. Lead anodic corrosion proceeds in two stages in sulfuric acid. Initially, Pb is oxidized to tetragonal PbO, as mentioned earlier; then, in the second stage, this is oxidized to PbO<sub>2</sub>. If this process is performed in solid state,  $\alpha$ -PbO<sub>2</sub> forms; however,  $\beta$ -PbO<sub>2</sub> can be formed by a dissolution-precipitation mechanism.<sup>19,20</sup> The oxide species are O<sup>2-</sup> anionic conductors; additionally, there is evidence from studies in batteries that PbSO<sub>4</sub> is a Pb<sup>2+</sup> cationic conductor.<sup>21</sup>

Passivation of lead also occurs in a range of other media, the most important of which is carbonate/bicarbonate as these equilibria are commonly

encountered in natural environments.<sup>22</sup> The passivation sequence on anodic polarization is similar to that in sulfuric acid except for the formation of lead carbonate instead of lead sulfate. Thus, Pb may be directly oxidized to PbO or Pb(OH)<sub>2</sub>, which then reacts with CO<sub>2</sub> (in the atmosphere) or bicarbonate/carbonate ions (in solution) to form protective PbCO<sub>3</sub>; at higher potentials, PbO<sub>2</sub> is formed. The rate of growth of the passive carbonate film is dependant on the concentration of carbonate in solution. However, unlike in sulfuric acid, the passivation process in carbonate media is essentially irreversible. Although pitting in sulfuric acid is possible (e.g., by perchlorate ions),<sup>23</sup> it is not the common degradation mechanism. However, in carbonate media, pitting is observed with a number of species in solution, including perchlorate<sup>24</sup> and nitrate.<sup>25</sup>

In summary, lead is passive at higher potentials at all pH, forming lead dioxide, which is a defect anion conductor. At intermediate potentials and in solutions of near-neutral to acid pH, lead generally passivates by formation of a salt film characteristic of the solution, for example, PbSO<sub>4</sub> in solutions of sulfuric acid. In such cases, the corrosion rate of lead tends to be controlled by the chemical dissolution of the corrosion product (salt film) and not by the potential. At intermediate potentials and high pH, lead will tend to dissolve forming the plumbite ion HPbO<sub>2</sub><sup>-</sup>. In strong alkali (1 M NaOH), formation of Pb(OH)<sub>2</sub> occurs at less positive potentials, which transforms to PbO according to a nucleation and growth mechanism under diffusion control.<sup>10</sup>

### 3.11.2.4 Corrosion Products

The nature (composition and morphology) of the corrosion product on lead will very frequently enable a good interpretation of the environment in which the material was exposed. However, note that lead dioxide cannot form under ordinary environmental conditions and that other metals cannot polarize lead sufficiently for it to form. Lead dioxide corrosion products can, therefore, only be produced by external polarization, either deliberately (as in a battery or anode) or accidentally (e.g., via stray currents).

From an inspection of the more common compounds of lead, it will be seen that, in many environments, the corrosion product will be relatively insoluble (Table 4). Often, however, compact protective films are prevented from forming on the surface of the metal. The nature of the film is influenced by the mode of crystallization, and in the case of the

**Table 4** Solubility of lead compounds

Compounds of lead	Formula	Solubility at 25 °C (g dm <sup>-3</sup> )
Acetate	(CH <sub>3</sub> COO) <sub>2</sub> Pb	550
Formate	(CHOO) <sub>2</sub> Pb	16
Nitrate	Pb(NO <sub>3</sub> ) <sub>2</sub>	600
Chloride	PbCl <sub>2</sub>	1 × 10 <sup>-4</sup>
Hydroxide	Pb(OH) <sub>2</sub>	4 × 10 <sup>-15</sup>
Carbonate	PbCO <sub>3</sub>	3.3 × 10 <sup>-14</sup>
Basic carbonate	2PbCO <sub>3</sub> Pb(OH) <sub>2</sub>	3.3 × 10 <sup>-14</sup>
Sulfate	PbSO <sub>4</sub>	1 × 10 <sup>-8</sup>
Sulfide	PbS	3.4 × 10 <sup>-28</sup>
Phosphate	Pb <sub>3</sub> (PO <sub>4</sub> ) <sub>2</sub>	10 <sup>-55</sup>
Oxide	PbO	Insoluble
Dioxide	PbO <sub>2</sub>	Insoluble

Source: Weast, R. C., Ed. *Handbook of Chemistry and Physics*, 57th ed.; CRC Press: Boca Raton, FL, 1989; pp B68–B146.

lower oxides, for example, frequently little protection is afforded. Lead dioxide often forms a good adherent film, especially when it is produced from a sulfate film or other adherent compounds during anodizing. Concentrated hydrochloric acid gradually dissolves it to form hexachloroplumbic acid, and with alkalis, plumbites are formed. With sparingly soluble salts of lead, the compactness of the deposits is likely to be strongly influenced by the concentration of the relevant anion; with low concentrations tending to result in imperfect coatings.

### 3.11.2.5 Galvanic Corrosion

Lead is relatively noble compared with most other metals in common use, apart from copper, and therefore, there is normally little concern about its galvanic corrosion as it will usually be the cathode in a coupled system. Where it is anodic, it will often not corrode significantly due to the formation of protective corrosion product films. However, increases in temperature may cause changes in the porosity of the protective film, or a phase change that, consequently, reduces its protective function. For example, at 75 °C, lead was found to be anodic to steel in seawater and groundwater because of a polarity reversal.<sup>26</sup> However, the expected order of potentials was restored if the water also contained a Bentonite clay suspension.

There are continuing concerns regarding galvanic corrosion involving lead in drinking water systems, where lead-containing solders are traditionally used (but are now being phased out). Particularly, in plumbo-solvent soft waters, lead is leached out from solders in measurable quantities that may be harmful to health.<sup>27</sup> Clearly, the best solution to this problem

is not to use lead; however, for the large numbers of historic properties where lead is still present in pipe-work, inhibition of this form of attack, for example, using silicates or phosphonates, is possible.<sup>28</sup> However, the ratio of chloride to sulfate is critical in controlling the leach rate of lead, and water utilities need to take note of this also in order to minimize the lead solubility of the water supply.<sup>29</sup>

## 3.11.3 Corrosion

### 3.11.3.1 Atmospheric Corrosion

Lead has been (and especially in historic and prestige properties, still is) used for roofing, gutters, flashings, downspouts, etc. and exhibits excellent resistance to air (dry or humid) and rain water, producing, after an initial period of time, an attractive patina. Initially, an oxide (PbO) is formed, which then converts by reaction with atmospheric carbon dioxide to plumbonacrite (Pb<sub>5</sub>O(OH)<sub>2</sub>(CO<sub>3</sub>)<sub>2</sub>) and hydrocerussite (Pb<sub>3</sub>(OH)<sub>2</sub>(CO<sub>3</sub>)<sub>2</sub>).<sup>30</sup> In atmospheres containing sulfur dioxide from industrial pollution, the general sequence of corrosion product (patina) formation is: lead oxide → basic lead carbonate → normal lead carbonate → normal lead sulfite → normal lead sulfate.<sup>31</sup> Lead is found to be reactive to common atmospheric gases, NO<sub>x</sub>, SO<sub>2</sub>, CO<sub>2</sub>, as well as the vapors of carboxylic acids.<sup>32</sup> As noted earlier, outdoor exposures were found to produce anglesite (PbSO<sub>4</sub>) and/or cerussite (PbCO<sub>3</sub>) while indoor exposures often produced lead carboxylates, due to higher levels of organic acid vapors from wood and wood products. Excluding the carboxylates, these corrosion products have a low solubility and are protective; however, they can produce a white flocculant 'run-off' in wet weather, which can stain surrounding surfaces in the very early stages of exposure.<sup>33</sup>

In marine environments, the initial oxide film reacts with sodium chloride when wet to produce basic lead chloride, which may result in corrosion of adjacent materials such as aluminum.<sup>34</sup> In such environments, the patina stabilizes, but takes approximately twice as long as in other atmospheric environments. A common treatment for new lead is a resin-based patination oil, which suppresses the formation of basic carbonates, allowing the slow controlled growth of a strongly adherent normal carbonate patina from the outset.<sup>35</sup>

Because of increasing concerns about lead in the environment, corresponding concerns regarding the release of lead from buildings are also evident. Thus,

lead ions can be introduced into the biosphere via corrosion and subsequent run-off of  $\text{Pb}^{2+}$  species, primarily from the solubility of cerussite (lead carbonate), hydrocerussite (lead hydroxy carbonate), and anglesite (lead sulfate) in rainwater. After an initial induction period, the measured release rate for lead ions was found to be  $10^{-5}$  moles of Pb per liter, or precipitation run-off per square meter of lead surface (i.e.,  $2.1 \text{ mg dm}^{-3}$ ) in both marine and rural locations,<sup>35</sup> which corresponds to a corrosion rate of about  $0.3 \mu\text{m year}^{-1}$  in these atmospheres.

It has been known for centuries that certain species of wood are 'more aggressive' to lead than are others, and this is now understood to be caused by the breakdown of cellulose species in the timber to volatile organic compounds (VOCs), especially acetic acid.<sup>36</sup> These can be liberated by new wood, especially oak, and also by varnishes, glues, urea formaldehyde, plastics, fabrics, and drying-oil paints, which can liberate fumes for a considerable time after application. Acetic acid in the 100–200 ppb range strongly accelerates the corrosion of lead, giving a corrosion product containing lead acetate–oxide–hydrate ( $\text{Pb}_3\text{O}_2(\text{CH}_3\text{COO})_2\text{H}_2\text{O}$ ) as well as cerussite and hydrocerussite.<sup>37</sup> The corrosion rate was found to be independent of relative humidity from 45% to 95% RH. This effect of VOCs on lead corrosion is significant not only in the context of buildings, but also in museums for display of historic artifacts.<sup>38</sup> However, the use of fatty acid soaps, such as sodium decanoate, successfully provides 99.9% inhibition to corrosion, by the formation of lead soaps, which are well known as corrosion inhibitors.<sup>39</sup>

### 3.11.3.2 Water

#### 3.11.3.2.1 Distilled and condensed water

In distilled water free from dissolved gases, corrosion is slight though significant; however, the rate of corrosion is increased by the presence of oxygen. Small amounts of dissolved oxygen and carbon dioxide cause rapid attack because the formation of a continuous protective film of lead carbonate does not occur. At moderate  $\text{CO}_2$  concentrations, passivation of the lead surface occurs because of  $\text{PbCO}_3$  formation, but in high- $\text{CO}_2$  contents, corrosion is increased because of the formation of soluble lead bicarbonate.<sup>40</sup>

Condensation corrosion is a common cause of failure in lead-work on buildings. Trapped water is evaporated from and condensed on the underside of the lead during thermal cycling in the environment. This repeated condensation causes the production of

lead oxide and lead hydroxide, which migrates away from the surface, leaving it unpassivated. Subsequent reaction with  $\text{CO}_2$  in the atmosphere produces copious quantities of basic lead carbonate, resulting in blistering, perforation, and finally, disintegration of the lead.<sup>41</sup> Adequate ventilation and adherence to codes of practice are essential to prevent this.<sup>42</sup> Lead sheet can also crack through thermal fatigue, and hence, admit water into a building structure. This is a consequence of over-fixing the lead, using sheets which are too large, or of using lead containing insufficient copper, and can be eliminated by correct installation.

#### 3.11.3.2.2 Natural waters

The European Union directive on the reduction of hazardous materials<sup>43</sup> stipulates that lead is no longer permitted for use in water supply, either as pipework or in solders. Where it is encountered in old buildings, its replacement is strongly recommended. However, because of the long life of existing installations, water may be conveyed through existing lead pipes, or pipes secured using lead-containing solders, for years to come. This may not be hazardous if the waters contain sufficient carbonate, sulfate, or silicate, and are alkaline. The current UK limit for lead in cold water drawn from a water supply tap is 25 ppb (the US limit is lower at 15 ppb); anything above these levels is actionable. Soft waters invariably dissolve lead to some extent, and raised levels of organic acids will render even harder supply waters plumbo-solvent.<sup>44</sup> Thus, water treatments to reduce lead solubility are required.

Lead corrodes slightly in most supply waters dependent primarily on the solution pH. The presence of oxygen and oxidizers in the aqueous medium affects the corrosion resistance of the metal more in acidic waters.<sup>45</sup> The most common treatments given to water are to increase the pH (reduce acidity) and remove organic acids; this is easily carried out by flocculation (e.g., with aluminum sulfate) and alkalinization (e.g., with calcium hydroxide or carbonate), which will encourage the formation of a protective carbonate scale.<sup>46</sup> Silicate and orthophosphate treatments reduce lead solubility; however, the common use of zinc orthophosphate to control corrosion of steel and cast iron water mains may increase lead corrosion rates.<sup>47,48</sup> In more saline waters, including seawater, lead usually has a good corrosion performance owing to the formation of the normal passive film of hydrocerussite ( $\text{Pb}_3(\text{OH})_2(\text{CO}_3)_2$ ) together with  $\text{Pb}(\text{OH})\text{Cl}$  and  $\text{PbCl}_2$  carbonate–chloride

double salts;<sup>49</sup> however, corrosion rates are linked to the activity of  $\text{Cl}^-$  ions, particularly in flowing solution.<sup>50</sup>

### 3.11.3.3 Buried Structures

#### 3.11.3.3.1 Stray-current corrosion

Stray currents are a source of damage to all buried metal structures, and lead pipes and cable sheaths are particularly susceptible. Although lead can corrode under cathodic (alkaline) conditions, it is generally the anodic sites on the pipe or cable sheath that are attacked. Lead is considered to be endangered if the current density is more than  $25 \text{ mA m}^{-2}$ . This is influenced by the conductivity of the soil, which is largely determined by the moisture content, but may be affected by salting of roads in winter. Non-metallic links in pipework may break electrical continuity. This will produce more numerous corrosion sites, but they are frequently less intense.<sup>51</sup> The surface will normally be covered with a mostly whitish corrosion deposit associated with either a smooth pitted surface or a more general rough etched appearance.<sup>40</sup> The corrosion product may comprise oxides, carbonates, hydroxides, and  $\text{PbCl}_2 \cdot \text{Pb(OH)}_2$  and  $\text{PbCl}_2 \cdot 6\text{PbO} \cdot 2\text{H}_2\text{O}$  have additionally been identified. Stray alternating current can also markedly increase corrosion rates,<sup>52</sup> and the use of lead pipes for electrical grounding has resulted in serious corrosion.<sup>51</sup> Electrolytic corrosion may also occur on the inside of cable sheaths by the passage of current from the cable sheath to the wire.<sup>51</sup> No protective coating is fully effective, but many give good protection with modern systems using polymers.<sup>53</sup>

#### 3.11.3.3.2 Underground corrosion

Lead has a long history of use underground in buried structures; historically for water supply, more recently for lead sheathed electrical cables. Corrosion is promoted by stray currents, local inhomogeneities in the lead, galvanic corrosion with another metal, and the environment of the soil.<sup>40</sup> Thus, soils may differ in water content, degree of aeration, or the presence of various chemicals or bacteria, and these can cause local or extensive corrosion of lead. Historically, extensive long-term tests have been conducted on lead in soils, and these data are still valid.<sup>54,55</sup> The worst combination of soils is wet clay and cinders (ashes from coal combustion). The carbon in the cinder acts as an efficient cathode and severe anodic corrosion takes place in the clay environment. Moisture held in the clay permits the passage of relatively

high currents. Anodic corrosion can occur when cables are in contact with dissimilar metals, such as steel support racks or copper bonding ribbon. A new (clean) section of cable may also become anodic to an old (passivated) cable and can then corrode.

Sandy soils and loams of high permeability are less aggressive because water tends to be mobile, thereby reducing concentration cells, and frequently drains readily to allow free movement of oxygen, thus reducing the effect of differential aeration cells. Where air circulates freely, a stable patina is often formed. Very large-grained soils are normally good for the reasons aforementioned, but under certain conditions, severe localized pitting can be caused by differential aeration (e.g., caused by differing degrees of soil density and compaction). Soils of low permeability, such as clays and silts, tend to be most corrosive; however, if the soil becomes deaerated the corrosion rate may fall; under such environments, microbial effects, due to sulfate reducing bacteria, often become important and corrosion can then become severe. Trenches are often lined before cable laying and backfilled after laying, with materials such as sand and crushed chalk, in order to encourage good drainage and ensure a consistent and benign local environment.

Sulfates, silicates, carbonates, colloids, and certain organic compounds in soils act as inhibitors if evenly distributed.<sup>40</sup> Nitrates tend to promote corrosion, especially in acid soil waters, due to cathodic depolarization and to the formation of soluble nitrates. Alkaline soils can cause serious corrosion with the formation of the plumbite anion, which decomposes to give  $\text{PbO}$ . Organic acids and carbon dioxide from rotting organic matter also have a strong corrosive action. Pitting corrosion in most groundwater/soil environments does not occur in the traditional meaning of the term; however, areas of nonuniform, general attack did occur, resulting in pitted surface morphologies.<sup>56</sup>

Calcium hydroxide leached from incompletely cured concrete causes serious corrosion of lead. This is because carbon dioxide reacts with the lime solution to form calcium carbonate, which is practically insoluble. Carbonate ions are therefore not available to form a passive film on the surface of the lead.<sup>40</sup> Typically, thick layers of  $\text{PbO}$  are formed, which may show seasonal rings of litharge (tetragonal  $\text{PbO}$ ) and massicot (orthorhombic  $\text{PbO}$ ).<sup>57</sup>

To prevent underground corrosion, lead was traditionally protected with coatings of tar, bitumen, resin, etc.; recently, however, polymeric materials (such as polyvinyl chloride, polypropylene, etc.) are

preferred. No coating is wholly effective unless they completely insulate the metal from corrosive agents and stray currents. The most successful method of protection for lead cables is cathodic protection. It is effective at a potential of  $E^\circ = -0.8\text{ V}$  or about 0.1 V more negative than its equilibrium potential in the soil in question;<sup>58</sup> both impressed currents or sacrificial anodes have been used. Excessively negative potentials can increase the pH of the environment, thus causing corrosion.

Sulfate-reducing bacteria in soils can produce metal sulfides and  $\text{H}_2\text{S}$ , which results in the formation of conductive lead sulfide and increased corrosion rates;<sup>59</sup> deep pits containing a black mass of lead sulfide have also been observed. Other microorganisms may also be involved in the corrosion of lead in soil, including other bacteria and fungi.<sup>60</sup>

Interest in lead as a possible barrier material for use in underground repositories for nuclear waste has prompted a number of studies. Repository environments with static groundwater would have very low oxygen contents and high ionic strengths and, under these conditions, lead would corrode at an unsuitably high rate. However, if the repository is flooded and oxygen levels increase, then lead might be acceptable.<sup>61</sup> Mass loss tests, supported by electrochemical polarization experiments, were carried out in natural and simulated groundwater, and in a range of specific salt solutions.<sup>62</sup> Corrosion rates in aerated conditions varied between  $1\text{--}3\text{ }\mu\text{m year}^{-1}$  in groundwater (which is acceptable) to over  $600\text{ }\mu\text{m year}^{-1}$  in sodium acetate and over  $380\text{ }\mu\text{m year}^{-1}$  in sodium nitrate (which is very high and unacceptable). Corrosion rates in bentonite clay suspensions likely to be used as repository backfill were  $10\text{--}15\text{ }\mu\text{m year}^{-1}$  and deemed to be acceptable.

### 3.11.3.4 Acids

#### 3.11.3.4.1 Mineral acids

Traditionally, sulfuric acid was made, stored, and conveyed in lead; this is because its corrosion resistance at moderate temperatures and over almost all the concentration range of the acid is excellent, provided that the protective sulfate film is not disrupted. Rupture of the sulfate film may be caused by erosion as a result of high-velocity liquids and gases containing acid spray. In such an environment, acid-resistant brick is often used with a liner of lead in between the brick and the (usually steel) vessel. Thermal cycling may also disrupt the film by thermal fatigue. The corrosion rate of lead is generally less

than  $125\text{ }\mu\text{m year}^{-1}$ , below about 55% concentration up to its boiling point ( $130^\circ\text{C}$ ), while acid concentrations to 80% have similar corrosion rates below  $100^\circ\text{C}$ . Above an acid concentration of 85%, the corrosion rate of lead increases to unacceptable values.<sup>62</sup> Lead is no longer used for this service in industry, its place having been taken by passive alloys such as tantalum, zirconium, specialist stainless steels, and nickel-based alloys.<sup>63</sup>

Nitric acid readily attacks lead if dilute, and the metal should not even be used for handling nitrate or nitrite species, except at extreme dilutions and preferably with a passivating reagent such as a sulfate, which will confer some protection. Corrosion decreases to a minimum at 65–70%  $\text{HNO}_3$ , and lead has been used for storage of nitric acid in the cold at this concentration.<sup>40</sup> Hydrochloric acid should generally be regarded as aggressive to lead and its use cannot be recommended, although a satisfactory life has been obtained with acid of up to 30% concentration at ambient temperature and 20% concentration at  $100^\circ\text{C}$ .<sup>40</sup> Resistance of lead to corrosion by HCl is presumably due to the formation of a protective film of lead chloride, which is only slightly soluble at these concentrations combined with its high overpotential for hydrogen evolution. In mixed hydrochloric and hydrofluoric acids (e.g., used for pickling steel) the behavior of lead is unreliable unless the lead is initially passivated in hydrofluoric acid first.

The remaining use of lead in industrial processes is as an anode in electrowinning and as an inert anode in electroplating, and for these applications, there are few economic alternatives. Lead has good resistance to phosphoric and chromic acids (e.g., in chromium plating), and at high current densities, will tend to passivate anyway with the formation of lead dioxide.

#### 3.11.3.4.2 Organic acids

Lead is attacked by most organic acids, which produce soluble lead salts, particularly in the presence of air or other organic oxidants. Aqueous acetic acid, solutions containing acetates, and acetic acid vapor all rapidly corrode lead and should be avoided if possible. During corrosion, the protective film is dissolved yielding lead salts of the organic acid. These are susceptible to rapid carbonation in the presence of  $\text{CO}_2$  and water, forming basic lead carbonate, which, in these circumstances, does not form a passive film.

Studies of the electrochemical behavior of lead at  $25^\circ\text{C}$  in acetic, lactic (0.01–1.0 M), oxalic, and tartaric (0.01–0.15 M) acid solutions demonstrated that

lead is readily soluble both in acetic and lactic acid solutions up to 2000 mV.<sup>64</sup> In these acids, anodic dissolution appears to be under charge transfer control, with lactic acid more aggressive than acetic acid with lead passivating at higher potentials. However, in oxalic and tartaric acid solutions a dependence on the acid concentration is evident. Thus, above a certain specific concentration, an anodic current peak is followed by a reduction in current associated with the formation of a passivation salt film that consisting of the oxalate or tartrate species, respectively. As noted above, corrosion by organic acids is important in the construction sector and also in the conservation of historic artifacts.

### 3.11.3.5 Lubrication Oils

White metal (tin–lead) bearings do not normally fail due to corrosion, but where this has occurred, it has been associated with the generation of acidity in the lubricant, the production of peroxides, and the presence of air. Peroxides appear to be the controlling factor, but corrosion is also reduced in the absence of air. The corrosion product generally consists of basic lead salts of organic acids.<sup>65</sup> The presence of residual organic acids is thought to be the main cause of the corrosion of terne (lead) plated steel when used as fuel tanks.

### 3.11.3.6 Miscellaneous Environments

As can be seen from the Pourbaix diagram, lead has no stable passive species at  $\text{pH} > 10$ –11, and hence, lead is not particularly resistant to dilute alkalis, and will dissolve freely as the plumbite oxyanion. Where free access to carbon dioxide is available, a passivating salt film of lead carbonate may form. However, lead is susceptible to lime drips from fresh concrete and cement mortar, which will tend to disrupt the lead carbonate film formation. Lead can tolerate concentrated alkalis such as KOH to 50% and up to 60 °C and NaOH to 30% and 25 °C, although it is explicitly not used for this purpose.

Lead is not generally attacked rapidly by solutions that contain anions, where the lead salt is sparingly soluble, and hence, where lead can passivate by the formation of a salt film. Thus, only nitrates and, to a lesser extent chlorides, are corrosive. The presence of nitrate tends to pit lead, for example, in carbonate solution.<sup>22</sup> In sodium chloride, the corrosion rate increases with concentration to a maximum in 0.05 M solution, then decreases because of the

formation of a relatively porous film  $\text{PbCl}_2$ . Control of the cyclic voltammetry conditions allowed the development of a relatively thick and more protective layer.<sup>66</sup> In potassium bromide, adherent deposits are formed, and the corrosion rate increases with concentration. The attack in potassium iodide is slow in concentrations up to 0.1 M, but in concentrated solutions rapid attack occurs, probably owing to the formation of soluble  $\text{KPI}_3$ . In dilute potassium nitrate solutions (0.001 M and below) the corrosion product is yellow and is probably a mixture of  $\text{Pb}(\text{OH})_2$  and  $\text{PbO}$ , which is poorly adherent. At higher concentrations, the corrosion product is more adherent and corrosion is somewhat reduced.<sup>67</sup>

## 3.11.4 Specific Applications

### 3.11.4.1 Lead Anodes

Anodes for electroplating and for electrolysis of brine are frequently made of lead and lead alloys. This is because the formation of a passive film of lead dioxide at high anodic potentials where conventional passive alloys, such as chromium containing materials, would be destroyed by transpassive dissolution. Nevertheless, there is generally a very slow continued corrosion, which leads to thickening of the  $\text{PbO}_2$  film. The resulting stresses caused by growth of the oxide layer can cause it to crack and disbond, releasing  $\text{PbO}_2$  particles into the electrolyte. Alloying elements are frequently added for strength and to stabilize the film; rolled or extruded alloys are generally found to be more resistant to this form of degradation than are cast alloys.

Lead–silver (1–2% Ag) anodes for cathodic protection may be used in brine and seawater applications for cathodic protection of ships and dockside structures<sup>68,69</sup> at current densities of up to  $120 \text{ A m}^{-2}$ , although in many applications these have now been superseded with platinum-doped titanium or niobium alloys, which can operate at still higher current densities.

Lead–silver, lead–tin, lead–calcium–tin, lead–calcium–silver, and lead–tin–silver are all used for electrowinning, which is generally carried out using sulfuric-acid-based electrolytes. These alloys have replaced the more traditional lead–antimony compositions due to requirements of higher purity in the deposits. In all electrowinning applications, it is essential to keep the potential of the anode well above the  $\text{PbO}_2/\text{PbSO}_4$  equilibrium potential, otherwise rapid corrosion will occur.<sup>69</sup> Electrochemical

studies of electrowinning anodes have been extensively studied and are focused on (a) reduction of anode corrosion rate, (b) reduction of (lead and other metal) contamination in the deposit, and (c) improved current efficiency.

For example, the efficiency and corrosion resistance of calcium- and silver-containing alloys appears to depend on the nature of the  $\text{PbO}_2$  passive layer and its electronic and ionic conductivity.<sup>70</sup> The corrosion rate and current efficiency of anodes can be improved significantly by the incorporation of minor amounts of foreign species in the electrolyte. Thus, preconditioning of anodes in a fluoride solution prior to use can result in a compact and more protective  $\text{PbF}_2/\text{PbO}_2$  bilayer that is more corrosion resistant.<sup>71</sup>

The corrosion rates for lead-silver anode corrosion rates in zinc electrowinning solutions were studied at a range of current densities from 2500 to 10 000  $\text{A m}^{-2}$ . Increases in acid concentration and temperature caused increases in corrosion rate, whereas in the absence of bath additions, the rate was independent of current density.<sup>72</sup> Chloride ions increased the corrosion rate, while fluoride preconditioning reduced it, but only in the presence of manganese. The presence of small concentrations of cobalt and manganese ions can reduce the corrosion rate of electrowinning anodes considerably. The effect appears to be related to an increase in the oxygen evolution kinetics that reduces cell overvoltage and causes less disruption of the  $\text{PbO}_2$  passive layer.<sup>73</sup>

Traditional chromium plating uses lead-tin or lead-antimony alloys as the anode material, although coated passive metal anodes (e.g., platinized Ti, Zr, Nb, and Ta) have recently been advocated.<sup>74</sup> Lead anodes offer processing advantages in that they can be formed or cast to conform to the surface to be plated, and hence give an even current density and uniform coverage of coating. The electrochemistry of anodes containing tin, antimony, and silver have been studied in electrolytes similar to chrome plating baths. In chromic acid, a passive film of  $\text{PbCrO}_4$  forms at very low overpotentials, and the subsequent formation of  $\text{PbO}_2$  is masked by oxygen evolution. The effects of alloying additions were found to be minor, although antimony raises the passive current substantially and silver reduces the overpotential of oxygen evolution by about 0.2 V.<sup>75</sup> As for electrowinning anodes, the quiescent (nonpolarized) corrosion rate can be very high and it is recommended that anodes are connected at all times. It has been found that 0.5  $\text{g l}^{-1}$  of magnesium fluosilicate suppresses corrosion without affecting the plating process.<sup>76</sup>

### 3.11.4.2 Lead-Acid Battery

Lead-acid batteries comprise by far the single most important worldwide application for lead. The technology of lead-acid batteries is still under constant improvement and is technically still very much relevant;<sup>77</sup> this section briefly discusses very general aspects of the technology. Lead-acid batteries typically consist of lead alloy supports, which carry an electrochemically active mass, the composition of which differs between positive and negative plates, and with the state of charge of the battery. Failure normally occurs in the positive grids of a battery. The main cause of failure is loss of contact between the grid and the active mass because of 'grid growth,' which is caused by the change in volume of the active material during the charge/discharge cycle, and by corrosion of the metal surface, which can be accelerated by stress. Batteries for automotive, electric vehicle, standby services, etc., all have different characteristics and requirements, which are met by battery grid design and choice of alloy.<sup>78,79</sup>

Traditionally, battery grids have been made from lead with 6–14% antimony, with a small amount of arsenic. High antimony alloys have a significant electrochemical disadvantage, that is, they reduce the overpotential for hydrogen evolution on the lead, leading to electrolysis of the electrolyte (to hydrogen and oxygen). Thus, batteries using traditional materials require regular maintenance (topping-up) via additions of distilled water. While alloys in the region of 5–6% antimony are still used in some industrial, deep discharge, and traction applications, high antimony contents have been largely replaced in automotive batteries by complex low antimony or antimony-free lead-calcium-(tin) alloys. Modern automotive batteries now use lead-calcium-based alloys that do not require topping up (provided they are operated within their electrical design parameters). This reduction in antimony content has been made possible by the introduction of additions of solidification nucleants, such as selenium and sulfur, which promote fine-grain structure. It is also increasingly common to find different alloys used in the positive and negative grids and optimized for these applications.

High antimony alloys exhibit high strength, good castability, and give good deep cycling performance. The latter requires that the active mass has good adhesion to the metal, is structurally stable during cycling, and does not passivate. Antimony reduces shedding of active material from the cells, produces a surface film of greater porosity, which becomes more

porous during cycling, promoting stability of the active mass. It has also been shown that  $\text{PbSO}_4$  is more reluctant to nucleate on antimonial lead.<sup>80</sup> Although corrosion rates may appear quite high, attack is normally of a general nature, which allows a satisfactory service life. This is because the eutectic is preferentially corroded, which reduces intergranular corrosion. Antimony reduces the oxygen overpotential on the positive grid, while  $\text{Sb}^{5+}$  ions migrate from the positive grid to the negative and be reduced to metallic antimony.<sup>81</sup> This reduces the hydrogen overpotential, leading to excessive gassing, consuming water from the electrolyte, reducing charge efficiency, and liberating stibine ( $\text{SbH}_3$ ). During overcharge, antimony increases the rate of formation of the inner corrosion layer on the positive grid.

Low maintenance batteries, which only require the addition of water infrequently in the second half of their service life, use low antimony alloys that typically contain less than 3% antimony, with some alloys containing as little as 0.6%. The most commonly used alloys have 1.3–1.8% Sb. They always contain As to assist hardening, and a nucleating agent such as Se or S with Cu. These are necessary because the coarse dendritic structure is prone to porosity and hot cracking during casting. The addition of nucleating agents gives a fine-grained structure with good corrosion resistance. Tin is often added to increase fluidity in casting alloys.

Lead–calcium–(tin) alloys are used in maintenance-free automotive starting, lighting, ignition (SLI) batteries, in stationary batteries, and some traction batteries. It is essential that the correct calcium content and a suitable calcium–tin ratio is used. In the binary lead–calcium alloys, a fine-grained structure with serrated grain boundaries is produced by a discontinuous precipitation reaction.<sup>82</sup> The addition of tin changes the nature of the precipitation reactions to give two areas of stability. One is with high calcium–low tin and the other is in the region below 1.8% tin and less than 0.07% calcium. Batteries made from these alloys have a much reduced rate of self-discharge compared with antimonial alloys, thus giving a longer shelf-life, and maintain a high discharge voltage throughout their life.

### 3.11.4.3 Reactor Coolants

Lead-based liquid metal coolants (using either liquid lead or liquid lead–bismuth eutectic) were first used in a nuclear reactor in the 1960s by the Soviets as an advanced, high power density, submarine propulsion

plant. Reactors designed using such coolants have some compelling advantages (e.g., operation at atmospheric pressure, boiling point greatly in excess of the reactor operating temperature, relative nonreactivity to water and air compared with liquid sodium) and comprise a candidate ‘Generation IV’ fast neutron reactor system as well as a candidate coolant system for fusion reactors. However, lead alloys are significantly more corrosive to constructional materials (e.g., steels) than is liquid sodium. This is due to dissolved oxygen in the lead that reacts with the containing material, as well as liquid metal embrittlement.<sup>83,84</sup> To avoid excessive oxidation of structural alloys, such as martensitic steels, it is necessary to control the oxygen activity to below  $10^{-24}$  atm, and this can be monitored by the use of electrochemical probes.<sup>85</sup>

### Glossary

**Allotropy** The existence of two or more different forms (allotropes) of the same element that are bonded in a different manner; allotropes are thus different structural modifications of an element.

**Gray tin** The low-temperature allotrope of tin having a cubic structure that is stable below  $\sim 13^{\circ}\text{C}$ . Note that the transformation from white tin to gray tin is sluggish and generally does not proceed significantly until the temperature is well below  $0^{\circ}\text{C}$ .

**White tin** The high temperature allotrope of tin having a body centered tetragonal structure that is stable above  $\sim 13^{\circ}\text{C}$ .

### Abbreviations

**AES** Auger electron spectroscopy

**SHE** Standard hydrogen electrode

**XPS** X-ray photoelectron spectroscopy

### 3.12.1 Introduction

#### 3.12.1.1 Physical Properties

The element tin is located in Group VI of the periodic table, lying above lead, with which it shares many properties. Tin, like lead, is one of the metals known from antiquity and highly prized for its ability to harden copper, forming bronze. There is evidence that tin was mined in the United Kingdom in

Cornwall from the early bronze age (2100–1500 BC). Certainly, by Roman times, tin from the western edge of Europe (mainly Cornwall and Spain) was traded widely throughout the known world. Tin ore resources are not widely distributed and production is mainly from two forms: (1) hard rock, typified by the Cornish deposits and similar ore bodies in Bolivia and Queensland; and (2) alluvial (placer) deposits, typified by the southeast Asian ore field stretching from Indonesia and Malaysia to Thailand.

Tin is allotropic with the normal, metallic ( $\beta$ ) form being body-centered tetragonal above the transformation temperature, that is,  $\sim 13.2^\circ\text{C}$ .<sup>1</sup> The lower temperature allotrope,  $\alpha$  or 'gray' tin, is cubic and forms with a significant volume change that tends to result in the disintegration of the material. However, the transformation is kinetically sluggish, although it can be encouraged by mechanical deformation and delayed, or effectively suppressed to lower temperatures, by impurities such as antimony, lead, and bismuth.<sup>2</sup> Gray tin normally appears as nodules of a friable material on the surface of the metallic form and resembles a corrosion product. Thus, the transformation is often not readily distinguishable from corrosion.<sup>3</sup> The transformation mechanism has been studied by high-resolution electron microscopy in order to obtain the lattice orientation relationship between the two allotropes.<sup>4</sup> Thus, the (011) plane of gray tin is parallel to the (001) plane of white tin, and the [211] direction of gray tin is nearly parallel to the [010] direction of white tin. This evidence supports a model for the  $\alpha$ -to- $\beta$  transformation that is partly martensitic and partly diffusional.

The use of unalloyed tin is restricted by its low melting point ( $232^\circ\text{C}$ ) and by its low tensile strength (15 MPa). On the other hand, its melting point, and its ability to 'wet' other metals (often by the formation of intermetallic compounds), facilitates its use as solder (for metal joining) and as a coating (for corrosion protection), while its softness and high ductility make it suitable for cold working and for bearing applications. Given its relatively low melting point, tin recrystallizes readily at room temperatures, and therefore, the effects of mechanical working are slight and arise from the differences in grain size and not from the effects of work hardening. The formation of tin whiskers is also thought to be a consequence of its low melting point, which results in the growth of fine threadlike structures, typically  $\sim 1\text{--}2\text{ }\mu\text{m}$  in diameter, with growth rates of up to millimeters per month under appropriate conditions.<sup>5,6</sup>

Given increasing health and safety concerns that lay severe limits on the use of lead in materials, there has been, for some time, a legislative driver for the development of essentially lead-free tin alloys. This has reintroduced problems relating to the formation of gray tin (at lower temperatures) and tin whiskers that were generally absent in lead-containing materials. For example, in the electronic industry, where tin-based solders are now widely used, whisker growth, in particular, can cause problems such as short-circuiting.<sup>7</sup>

### 3.12.1.2 Applications

The industrial use of tin is limited by its low strength and very limited solubility for most elements at room temperature. However, tin is essential in a number of alloys where it is a minor constituent (e.g., in copper–tin bronzes) and also where it is the major component (e.g., in pewter). The most important forms in which tin is used are

1. tin of more than 99% purity for specialist applications;
2. tin hardened by additions of 1–2% Cu or Sb;
3. pewter with 90–95% Sn, 4–8% Sb, and 1–2% Cu;
4. coatings for other metals, which may be pure tin or tin plus a codeposited species;
5. soft solders with tin and lead in all proportions;
6. lead-free soft solders with  $>90\%$  Sn and additions of silver, copper, bismuth, indium, or zinc;
7. bearing metals 'high tin' and 'head lead' with a wide range of proportions of tin, antimony, copper, and lead, or with tin (5–30%) in aluminum;
8. diecasting alloys containing 70–80% Sn with antimony, copper, and lead, either one of them or a combination.

The corrosion behavior of tin and tin alloys, whatever their form, is basically similar, except in the case of solders and bearing metals where the wide composition range and special duties of the materials give particular issues. The impurities likely to be present in nominally pure tin are unlikely to affect its corrosion resistance, except for minor effects on the rate of oxidation in air. Low aluminum contents, however, may result in a severe intergranular attack by water; the addition of antimony counteracts this effect. Although 0.1% magnesium appears to be tolerable, larger amounts produce effects similar to those of aluminum.<sup>8</sup>

Apart from the special uses in solders and bearings metal already referred to, and as coatings, tin and its alloys find employment where we can take advantage

of their physical properties and their fair resistance to tarnish and corrosion in near-neutral environments. Tin has traditionally been used in many food-grade applications, although such applications nowadays increasingly use cheaper materials, such as stainless steels and polymers. Tin pipe can be used to condense steam for high-purity distilled water, as a conveyor of beer and soft drinks, especially in coils through cooling media, and, in a larger size, as organ pipes. Some pharmaceutical and food products are packed in collapsible tin tubes, and tinfoil coverings are used on cork wads for jar and bottle closures. The tin alloy pewter is most valued for the decorative forms into which it is easily worked or cast, but it is also used for making drinking vessels and dishes.

### 3.12.2 Electrochemistry

#### 3.12.2.1 Thermodynamics

The Pourbaix diagram for tin, **Figure 1**, refers only to solutions in which the formation of soluble tin complexes (e.g., with citric acid) does not occur. Tin is a slightly active metal with its domain of stability below that of the hydrogen equilibrium; in theory, it will corrode in acid, evolving hydrogen gas. It is more noble than iron and nickel, but slightly less noble than lead, although in practice, passivity will alter this sequence. Tin shows a wide range of passivity

because of the stability of tin (IV) oxide,  $\text{SnO}_2$ , which is stable at a lower pH than is  $\text{PbO}$ . However, tin will dissolve as  $\text{Sn}^{2+}$  ions at  $\text{pH} < 2$  and as the corresponding (II)- or (IV)-valent oxy-anion species at  $\text{pH} > 11$ . Note, however, that in regions where, as shown in the diagram, the dissolution of tin is possible, the rate of corrosion may be very low. This is because the overpotential for hydrogen evolution on tin is high, particularly in acid solution. Thus, in a range of concentrations of  $\text{H}_2\text{SO}_4$ ,<sup>9</sup> the exchange current for the hydrogen evolution reaction was found to be  $10^{-11} \text{ A cm}^{-2}$  with a Tafel slope of 0.118 mV per decade current, indicating that a one-electron transfer reaction was rate controlling. In KOH solutions,<sup>10</sup> the exchange current was higher,  $3 \times 10^{-6} \text{ A cm}^{-2}$ , while the Tafel slope was similar to that in acid, 0.120 mV per decade current. Consequently, in alkaline or moderately acid solutions free from oxygen or oxidizing agents, the corrosion of pure tin may be barely detectable unless the tin is in contact with another metal that has a lower overpotential (higher exchange current density) for hydrogen evolution.

The passivity of tin in the middle pH range (i.e., between 3 and 10), its solubility in acids or alkalis (modified by the high hydrogen overpotential), and the formation of complex ions (especially with organic acids) are the bases of its general corrosion behavior. Other properties that have influenced the selection of tin for particular purposes are the

**Figure 1** Pourbaix ( $E$ -pH) diagram for tin in water at a dissolved concentration of  $10^{-5} \text{ M}$  tin species. Reproduced from HSC: Chemistry, version 6.12, Outotec Research Oy, Finland, 2007.

low toxicity of tin salts (that permit the use of tin in food-grade applications) and the absence of catalytic promotion of oxidation processes that may cause changes in oils or other neutral media affecting their quality or producing corrosive acids.

### 3.12.2.2 Dissolution

The electrochemistry of tin was extensively reviewed by Stirrup and Hampson in 1977.<sup>11</sup> As can be seen from the Pourbaix diagram, tin shows passivity by virtue of the formation of Sn(IV) oxide ( $\text{SnO}_2$ ), over an extended pH range from about 3 to above 10. Also, as previously indicated, the dissolution kinetics are slow, especially in acid, by virtue of a low exchange current density for hydrogen evolution.

At potentials just above its reversible value, tin dissolves under anodic polarization in acids initially as stannous ion ( $\text{Sn}^{2+}$ ). In 4–8 M sulfuric acid, this reaction has a Tafel slope of close to 40 mV per decade current, indicating a two-electron transfer reaction with a probable bisulfate ion intermediate.<sup>12</sup> The stannous ion is unstable in water at most values of pH (except in acid concentrations typically  $>1$  M), and at low concentrations, is hydrolyzed giving a number of species, depending on pH:  $\text{SnOH}^+$ ,  $\text{Sn(OH)}_2$ ,  $\text{Sn(OH)}_3^-$ , etc.; at higher tin concentrations, the complex species  $\text{Sn}_2(\text{OH})_2^{2+}$  and  $\text{Sn(OH)}_4^{2+}$  are prevalent.<sup>13</sup> The hydroxide complexes are well known to react with halides to give a number of Sn(II) hydroxy-halide complexes; however, these are only present in solution when the halide concentration is  $>10^{-3}$  M and at pH values  $<4$ . In alkaline conditions, tin initially dissolves as stannite ion,  $\text{Sn(OH)}_3^-$ , which is subject to the same speciation as a function of pH, as indicated earlier.

At higher potentials, Sn(II) is universally oxidized to Sn(IV) species. There are very little experimental data on this reaction; however, Sn(II) to Sn(IV) oxidation was studied in strong sulfuric acid and found to have first-order kinetics with respect to the dissolved species; an increase in  $\text{H}^+$  ion concentration decreased the reaction rate, while an increase in  $\text{SO}_4^{2-}$  had the opposite effect.

### 3.12.2.3 Passivation

Over the majority of the pH range, the passive film is generally assumed to consist of  $\text{Sn(OH)}_4$  or  $\text{SnO}_2$ ; however, in view of its very low solubility, data for the speciation of tin (IV) oxides and hydroxides in aqueous environments are very sparse. Indeed,

the formation of  $\text{SnO}_2$  as a passive film is one of the reasons for the excellent corrosion resistance of tin in noncomplexing aqueous environments.

In 4–8 M sulfuric acid, passivity is consistent with thin films of stannous oxide ( $\text{SnO}$ );  $\text{SnO}_2$  only formed at significantly more positive potentials.<sup>12</sup> Passive films on tin corroded at the open circuit potentials in 6.7 M nitric acid, 5.7 M hydrochloric acid, and 9 M sulfuric acid were analyzed using Mössbauer spectroscopy and found to consist of hydrated  $\text{SnO}_2$ ,  $\text{Sn}_4(\text{OH})_6\text{Cl}_2$ , and  $\text{SnSO}_4$ , respectively.<sup>14</sup>

Passive films on tin were studied using infrared and surface-enhanced Raman spectroscopy.<sup>15</sup> In 0.1 M NaOH solution,  $\text{Sn(OH)}_4$  was found to dominate, and further exposure to dry air was found to dehydrate the film to  $\text{SnO}_2$ , with the evidence of only a small amount of  $\text{SnO}$ . The passive film on 0.15 M NaCl solution (near-neutral) was found to consist only of  $\text{Sn(OH)}_4$ . However, angle-resolved X-ray photoelectron spectroscopy (XPS) was used to develop a model for the passive film on tin in 0.1 M KOH, and it was found that tin hydroxide was present only in the outer layers of the film. The inner layer consisted of  $\text{SnO}_2$ , with the evidence of  $\text{SnO}$  adjacent to the metal-oxide interface.<sup>16</sup> This appears to be consistent with results from phosphate buffer solutions (pH 4.3) where  $\text{Sn(OH)}_4$  was found along with a reduced species, either  $\text{Sn(OH)}_2$  or  $\text{SnO}$ , at the metal-oxide interface.<sup>15</sup> An electrochemical study of the anodic oxidation of tin was performed in carbonate-bicarbonate buffer solution at pH 8.9. From  $-0.1$  to  $1.2$  V (SCE), tin exhibited an essentially potential-independent, steady-state, passive current, which was found to be independent of flow conditions.<sup>17</sup> The results indicate that the anodic film grows according to the Mott-Cabrera model and is an oxygen ion conductor. Finally, the electrochemical passivation of tin was studied in citric acid buffer at pH 6.<sup>18</sup> Prepassivation was found to occur along with Sn(II) and Sn(IV) species, while full passivation was associated with Sn(IV) species only. The results indicated that, although the initial film formed coincided mainly with  $\text{Sn(OH)}_4$ , this transformed at longer periods of time to the more thermodynamically stable  $\text{SnO}_2$  species.

In summary, tin is found to passivate in aqueous environments from below pH 1 to above pH 12, forming an oxide film that consists of  $\text{Sn(OH)}_4$  or  $\text{SnO}_2$ . The latter oxide, which is more stable, may form either initially or transform gradually with time from the hydroxide. It is likely that a thin layer of Sn(II) species is stable at the interface between the passive film and the metal, although films consisting

predominantly of Sn(II) species are not observed except in high concentrations of the reducing acid.

### 3.12.3 Corrosion and Oxidation

#### 3.12.3.1 Atmospheric Corrosion

##### 3.12.3.1.1 Oxidation in dry air

Oxidation of tin in dry air is slow; the metal remains bright and interference colors are not developed below  $\sim 180^\circ\text{C}$ . On a rolled tin surface heated in air,<sup>19,20</sup> the thickness of the oxide grew according to the logarithmic law at temperatures of up to  $\sim 160^\circ\text{C}$  and according to the parabolic law at higher temperatures, for which the oxide was identified as SnO. For electropolished tin heated in oxygen at pressures of  $130\text{ N m}^{-2}$  and above, three stages of oxidation were observed at temperatures of up to  $220^\circ\text{C}$ :<sup>21–24</sup>

1. an initial sigmoid growth curve during nucleation;
2. a logarithmic growth curve when cavities acted as diffusion barriers;
3. erratic behavior caused by random film rupture.

The oxide formed was identified as SnO at temperatures down to  $75^\circ\text{C}$ . However, a mixture of SnO and SnO<sub>2</sub> is formed in dry air at lower temperatures, and in humid air, at temperatures of at least  $100^\circ\text{C}$ .<sup>25</sup> The electrochemical reduction analysis on tin oxidized in dry air at 125 and  $150^\circ\text{C}$  confirmed the presence of SnO with a thin surface layer of SnO<sub>2</sub>.<sup>26,27</sup> Small additions, for example, 0.1%, of indium, zinc, or phosphorus reduce the rate of oxidation, and the addition of antimony, thallium, or bismuth accelerates it.<sup>24</sup>

##### 3.12.3.1.2 Corrosion in humid air

In the absence of polluting gases or dusts, increasing relative humidity tends to increase the rate of oxidation<sup>28</sup> and may cause the development of interference colors. In an ordinary atmosphere, some corrosion product may be formed over time. However, tin products are not hygroscopic, and tin is not attacked at relative humidities of below 100% unless the dust falling on the surface is hygroscopic, or impurities in the metal are able to form a hygroscopic product. Indoors, in an unpolluted laboratory atmosphere, a gray film, increasing in weight linearly with time ( $4\text{ mg m}^{-2}\text{ day}^{-1}$ ), is formed, while in sheltered exposure (no rain) outdoors, the corrosion rate declined with time. The reflectivity of the surface is slowly lost if it is left untouched, but may be preserved by regular washing; in one experiment, when the surface was washed at intervals of 3 weeks, a water wash was adequate for

6 weeks, and although the use of soap was necessary thereafter, almost a complete preservation of reflectivity was achieved.

The impurities ordinarily present in the atmosphere do not appreciably affect the character of corrosion. No tarnishing effect is exerted by hydrogen sulfide, sulfur dioxide, and other acids in low concentrations, including formic, acetic, and other organic acids, which, when evolved from wood or insulating materials, are very often destructive to metals other than tin, in the confined spaces of electrical equipment or of packages. Chlorides accelerate corrosion and tend to form a white corrosion product containing oxychloride. The presence of some impurities, notably zinc, in the metal may cause tarnishing and a loss of brightness in atmospheres containing SO<sub>2</sub>.<sup>29</sup> The corrosion rate of electroplated tin on nickel in the presence of sub-ppm amounts of either SO<sub>2</sub> or NO<sub>x</sub> did not increase. However, a synergetic effect was found with both pollutants where the corrosion rate was increased significantly.

The atmospheric pollution prevailing in special industrial or laboratory locations may induce more severe corrosion, for example, the vapors from concentrated hydrochloric or acetic acid will etch tin, and moist sulfur dioxide will produce a sulfide tarnish, as will hydrogen sulfide at temperatures of above  $\sim 100^\circ\text{C}$ , and halogens attack tin readily.

When tin is fully exposed out of doors, corrosion is uniform, and the rate falls only slightly with time. The metal becomes dull and accumulates a compact layer of pale gray product, mainly stannous oxide. Rates observed during exposures in the United States for periods of up to 20 years were  $1.3\text{--}1.8\text{ }\mu\text{m year}^{-1}$  in industrial atmospheres (i.e., mainly polluted with sulfur dioxide),  $1.8\text{--}2.8\text{ }\mu\text{m year}^{-1}$  in marine atmospheres (i.e., mainly polluted with sea-salt), and less than  $0.5\text{ }\mu\text{m year}^{-1}$  in rural atmospheres (i.e., relatively unpolluted).<sup>30</sup>

##### 3.12.3.1.3 Atmospheric corrosion products

The corrosion of tin in various humid atmospheres has been examined using a number of surface analytical techniques, including XPS and Auger electron spectroscopy (AES).<sup>25,31,32</sup> While it is difficult to resolve the peaks of the oxide from those of the hydroxide, and hence, to establish their degree of surface hydration, there is a general agreement that both SnO and SnO<sub>2</sub> may be present depending on the temperature of exposure.

In atmospheres polluted with  $>100$  ppm nitrogen dioxide, tin nitrate was reported to form at 30–35%

RH.<sup>33</sup> In a mixed atmosphere containing more representative atmospheric conditions (40 ppb  $\text{H}_2\text{S}$ , 350 ppb  $\text{SO}_2$ , 500 ppb  $\text{NO}_2$ , and 3 ppb  $\text{Cl}_2$ ) at 81% RH, only tin oxides were found.<sup>34</sup> An XPS study on the films formed in  $\text{SO}_2$  and  $\text{NO}_x$  found only oxide species in  $\text{SO}_2$ , but a mixture of oxides and nitrates with  $\text{NO}_x$ . No synergy was noted between at-ppm concentrations of  $\text{SO}_2$  and  $\text{NO}_x$  at 85% RH.<sup>35</sup>

### 3.12.3.2 Corrosion in Acid

#### 3.12.3.2.1 Mineral acids

As the high overvoltage restricts hydrogen evolution, corrosion in organic acids or dilute nonoxidizing mineral acids is generally controlled by the rate of supply of oxygen.<sup>2,3</sup> In solutions of acid open to air, with specimens of size  $50 \times 20$  mm completely immersed, corrosion rates were, in a range of 0.1 M organic acids,  $400\text{--}500 \text{ g m}^{-2} \text{ day}^{-1}$ , and in 0.1 M hydrochloric or sulfuric acids,  $600 \text{ g m}^{-2} \text{ day}^{-1}$ . In the absence of oxygen, the rates in the two mineral acids were  $100\text{--}150 \text{ g m}^{-2} \text{ day}^{-1}$ , while they were negligible in the organic acids. Phosphoric acid forms a protective layer, and even in the presence of air, the corrosion rate is only  $\sim 20 \text{ g m}^{-2} \text{ day}^{-1}$ . Nitric acid corrodes tin freely even in the absence of oxygen; however, chromic acid forms a protective film. This film, which contains chromic oxide and tin oxides, will, after withdrawal from the acid, give some degree of protection against mildly corrosive conditions. Thus, hot solutions of chromic acid, alone or mixed with phosphoric acid, may be used as passivating media.

#### 3.12.3.2.2 Organic acids

Tin forms complex ions with many organic acids, including those commonly found in fruits (citric, oxalic, malic). This action has important effects on the galvanic behavior of tin. The normal electrode potential of tin is  $-0.136 \text{ V}$ , but the reduction of stannous ion activity resulting from the formation of complexes may depress the corrosion potential to make tin anodic to iron.<sup>36</sup>

The attack of tin by oxalic, citric, and tartaric acids was found to be under the anodic control of the  $\text{Sn}^{2+}$  salts in solution in oxygen-free conditions.<sup>37</sup> In a study of tin contaminated by up to 1200 ppm Sb, it was demonstrated<sup>38</sup> that the modified surface chemistry catalyzed the hydrogen evolution reaction in deaerated citric acid solution. Tin was found to corrode more rapidly in tartaric acid because of the reduction in the hydrogen overpotential; passivation was caused by a film of tin hydroxide or oxide.<sup>39</sup>

### 3.12.3.3 Corrosion in Near-neutral Conditions

Pure tin is completely resistant to distilled water, hot or cold. Local corrosion occurs in salt solutions that do not form insoluble compounds with stannous ions (e.g., chloride, bromide, sulfate, nitrate), but is unlikely in solutions giving stable precipitates (e.g., borate, monohydrogen phosphate, bicarbonate, iodide).<sup>40</sup> In all solutions, oxide film growth occurs and the potential of the metal rises. Any local dissolution may not begin for several days, but once it has begun, it will continue, its presence being manifested at first by small black spots and later by small pits. The movement of the solution tends to prevent pitting; stagnation, especially in crevices where the tin touches another solid surface, favors its progress. Contact with a more noble metal such as copper or nickel increases the number and intensity of pits; contact with metals such as aluminum and zinc gives cathodic protection.

As indicated earlier, the bicarbonate ion inhibits the process, which does not occur, therefore, in many supply waters; attack is most likely in waters that, by nature or as a result of treatment, have a low bicarbonate content and relatively high chloride, sulfate, or nitrate content. The number of points of attack increases with the concentration of aggressive anions, and ultimately, slow general corrosion may occur.

During the exposure of 99.75% tin to seawater for 4 years, a corrosion rate of  $0.0023 \text{ mm year}^{-1}$  was observed.<sup>41</sup> Corrosion in soil usually produces slow general corrosion with the production of crusts of oxides and basic salts. For example, the production of the significant quantities of the metastable corrosion product romarchite ( $\text{SnO}$ ) is commonly seen when studying pewter corrosion products from marine archaeological sites,<sup>42</sup> but is never seen, except transiently or as a thin interfacial phase, in passive films and atmospheric corrosion products.

### 3.12.3.4 Corrosion by Alkalis

The Pourbaix diagram indicates the possibility of attack by solutions of pH values above  $\sim 10.5$ , but the position of this limit is influenced by temperature, by the constitution of the solution, and by the surface condition of the metal. Corrosion will ensue if the surface oxide is significantly soluble, which will occur increasingly beyond pH 12.

Once corrosion begins, its rate is governed by the oxygen supply and temperature and is not greatly affected by the character of the alkali. Rates of attack

for specimens completely immersed in still solutions open to air are  $\sim 600 \text{ g m}^{-2} \text{ day}^{-1}$  at  $30^\circ\text{C}$  and  $1000 \text{ g m}^{-2} \text{ day}^{-1}$  at  $70^\circ\text{C}$ . In intermittent immersion such as is experienced in the cleaning of tinned ware by alkaline detergents, however, the rate of corrosion is affected by the nature and concentration of the solution, as these affect the time required for the removal of the oxide film at each fresh immersion.<sup>43</sup> Saturated ammonia solutions do not attack tin, possibly because of the negligible oxygen content, but more dilute solutions behave like those of other alkalis of comparable pH. In aerated alkaline conditions, 0.01–1 M NaOH, corrosion of tin was confirmed to be under cathodic control, and additions of other species, apart from chromate, were found to make little difference to the corrosion rate.<sup>44</sup>

The removal of oxygen from an alkaline solution, as by the addition of sodium sulfite, can prevent corrosion unless the tin is in contact with another metal, such as steel, from which hydrogen can be evolved. Additions of oxidizing agents in small amounts stimulate corrosion, but sufficiently large additions produce passivity. Alkaline chromate solutions in the passivating range produce a film containing chromium oxide, which has some protective value.<sup>19,45</sup>

### 3.12.3.5 Corrosion in Foodstuffs

Sulfide solutions, sulfurous acid, and some foodstuffs containing organic sulfur compounds produce stains of sulfide, but the rate of loss of metal is low.<sup>2,3</sup> Milk and milk products are usually without action, although local corrosion has been known to occur in dairy equipment. Beer initially dissolves a trace of tin and this may be sufficient to cause a haze in the liquor, but any corrosion usually slows to an insignificant rate after some time.

In general, near-neutral aqueous products are without action except for possible sulfide staining, or when there are dissolved salts present, some local corrosion. The slight acidity, which may develop in solutions of some organic compounds such as formaldehyde or alcohols can be tolerated. Many organic liquids, including oils (essential, animal, vegetable, or mineral), alcohols, fatty acids, chlorinated hydrocarbons, and aliphatic esters, are without action. The absence of any catalytic action of tin on oxidative changes is helpful in this respect. When, however, mineral acidity can arise, as with the chlorinated hydrocarbons containing water, there may be some corrosion, especially at elevated temperature.

**Table 1** Standard reduction potentials and galvanic series compared with tin

<i>Standard reduction potentials (vs. SHE)</i>	<i>Practical galvanic series in sea water</i>
$\text{Cu}^{2+} + 2\text{e}^- \Rightarrow \text{Cu}: +0.34 \text{ V}$	Graphite
$\text{Pb}^{2+} + 2\text{e}^- \Rightarrow \text{Pb}: -0.12 \text{ V}$	Passive stainless steels
$\text{Sn}^{2+} + 2\text{e}^- \Rightarrow \text{Sn}: -0.14 \text{ V}$	Copper alloys
$\text{Ni}^{2+} + 2\text{e}^- \Rightarrow \text{Ni}: -0.25 \text{ V}$	Tin (and tin-rich solders)
$\text{Fe}^{2+} + 2\text{e}^- \Rightarrow \text{Fe}: -0.44 \text{ V}$	Lead (and lead–tin solders)
$\text{Zn}^{2+} + 2\text{e}^- \Rightarrow \text{Zn}: -0.76 \text{ V}$	Steel and cast iron
$\text{Al}^{3+} + 3\text{e}^- \Rightarrow \text{Al}: -1.67 \text{ V}$	Aluminum
$\text{Mg}^{2+} + 2\text{e}^- \Rightarrow \text{Mg}: -2.37 \text{ V}$	Zinc
	Magnesium

### 3.12.3.6 Galvanic Corrosion

As indicated from the galvanic series, tin is less noble than copper and stainless steels, but more noble than most other elements in common use (Table 1). However, tin is usually ineffective as a sacrificial anode because of its very low self-corrosion rate, and generally, may be safely used in contact with most materials.<sup>46</sup> However, in the presence of species such as citric acid, which can form complex ions, tin will activate with its equilibrium potential moving to more negative values. This effect is important in the corrosion protection of steel cans with tinplate.

## 3.12.4 Applications

### 3.12.4.1 Tin Coatings

Interested readers are directed to the dedicated section on tin coatings elsewhere in this volume; only brief comments are provided here. Tin coatings may be applied either by hot-dipping from molten metal or by electroplating from either acid or alkaline solutions<sup>2,3</sup> or by metal spraying.<sup>47</sup> Also, tin may be codeposited during electroplating with a range of other elements such as nickel, cobalt, copper, and zinc, each of which gives rise to a particular property. Tin-plated steel is extremely widely used in the food and beverage canning industry as a container and relies on both the low corrosion rate of tin (can exterior) and the common potential reversal to steel in the presence of natural complexing agents (can interior). In practice, because of the high cost of tin, it is essential to use as thin a layer as possible. Thus, the corrosion protection afforded by the tin is usually supported by internal and external lacquering (organic coating) of the can, and it is therefore, the

organically coated tin that provides the full corrosion protection system for the steel substrate.

The thinnest tin coatings are most efficiently applied by electroplating; where this is likely to give pinholes, surface melt reflowing may be used to improve the performance. Where thicker coatings are required, usually for specialist applications, for example, hot dipping or metal spraying can be used. For example, traditional copper cooking utensils are frequently internally coated with tin to several tens of microns in thickness to prevent the interaction of copper with foods that can lead to the development of taints. The advantage of this process is that when the tin wears off, it can be easily replaced by redipping. Hot-dipped (and sprayed) coatings take advantage of the formation of tin-iron or tin-copper intermetallic species for excellent adhesion of the coating.

### 3.12.4.2 Solders

Alloys of tin with lead and/or a number of other elements comprise a class of jointing materials known as solders. Solders are used for cost-effective and efficient jointing of many materials, most commonly for copper alloys (e.g., heat exchangers) and steels (e.g., cans). Solders are generally characterized by their ability to flow across or 'wet' the metal to be jointed; such wetting is usually accomplished by the formation of intermetallic compounds between the solder and the substrate. Thus, tin forms  $\text{Cu}_6\text{Sn}_5$  and  $\text{Cu}_3\text{Sn}$  with copper alloys<sup>48</sup> and  $\text{FeSn}$ ,  $\text{Fe}_3\text{Sn}$ , and  $\text{FeSn}_2$  with steel.<sup>49</sup> The mechanical properties of these intermetallic species are critical; thus, they provide a metallurgical bonding between the jointed materials, but must not form brittle phases. Many types of tin-based solders are available, for example, Sn-Pb (traditional solders with compositions from 60/40, 50/50, 40/60 depending on use), Sn-Zn (for jointing aluminum), and Sn-Ag (lead-free solder for general use). In particular, for health reasons, there is an increasing use of low-lead, or lead-free solders, especially for joints in water supply systems and in food canning. These environmental concerns are now making the electronics industry also move to lead-free formulations.

Effective soldering requires a clean surface, free of contamination such as greases, oils, and water and the removal of the normal air-formed oxide on the material that is to be jointed. Typically, this is carried out initially by mechanical abrasion or solvent cleaning with the final removal of the tenacious surface oxide via a 'flux'. A flux is, by its nature, corrosive, and

hence, careful selection of the flux material is necessary. Otherwise, corrosion in service will be promoted locally.<sup>50</sup> It is, however, possible to select fluxes that are active when hot, but give noncorrosive residues when cold, for example, solid organic acids. If it is necessary to use more vigorous materials, such as zinc chloride, any residues must be fully removed. By the nature of their use as a jointing material, solders are usually presented to a corrosive environment as a small area within a much larger area of another metal. Thus, if the solder is anodic to the metal it joins, and if the corroding medium has good electrical conductivity, damaging corrosion is possible due to the unfavorable (small anode versus large cathode) anode-to-cathode area ratio.

Traditional lead-tin solders are anodic to copper, but soldered joints in copper pipes have been widely used without trouble for cold supply waters; possibly, corrosion is restricted by the deposition of cathodic carbonate scales and the formation of insoluble lead compounds. Hot supply waters tend to be more aggressive, but are likely to still give satisfactory service. However, electrolytes of sufficiently high conductivity, such as seawater, will cause corrosion of soldered joints in copper and copper alloys. In automotive radiators, antifreeze solutions have been alleged to cause corrosion, possibly because materials such as ethylene glycol sometimes detach protective deposits. Sodium nitrite, valuable as a corrosion inhibitor for other metals in a radiator, tends to attack solders, but sodium benzoate is safe, and in addition, protects the soldered joint against the action of nitrites.<sup>51</sup>

In environments in which tin is less readily corroded than lead, corrosion resistance of the alloy decreases as the lead content increases; the decrease may, in some circumstances, be sharp at a particular composition. In the more corrosive media, a sharp increase of corrosion rate is observed as the lead content increases beyond 30%. However, in waters with low contents of dissolved salts, the corrosion rate increases slowly with lead content up to ~70% and then rises more steeply. Selective dissolution of tin has been reported to occur in prolonged contact of solders with solutions of anionic surface active agents.<sup>52</sup>

In view of the known tendency for lead to be released in supply waters from conventional soldered joints,<sup>53</sup> there is an accelerating trend away from the use of lead-containing solders in contact with potable water, which is also being driven by legislation.<sup>54</sup> The effects of galvanic corrosion of one of the substitute alloys (Sn-3Ag) in contact with a number of other metals, including copper, have therefore been studied.<sup>55</sup>

### 3.12.4.3 Tin Interconnections

Tin-based jointing alloys (solders) are the materials of choice for connections and interconnections in the electronics industry. Traditionally, a eutectic tin-lead (67Sn–33Pb) alloy has been used, but the legislative driver for the removal of lead has also affected this sector, which has now effectively moved to encompass the use of lead-free solders. The performance characteristics of electronic connectors is dominated by (1) local galvanic corrosion between different metals, either in contact or as a coating and influenced by applied direct currents; (2) the corrosion of the soldering alloy, which is controlled largely by the presence of residues from various manufacturing and assembly operations; (3) fretting forms of corrosion damage induced by repeated making and breaking of electrical contacts; and (4) the formation of metal whiskers of tin that tend to be produced as a result of applied stress and voltage. All of these phenomena can lead to either a reduction of performance or an outright failure via a variety of mechanisms,<sup>55</sup> the most important of which are increases in the contact resistance with time and short-circuit current paths between contacts because of corrosion products, soldering residues (i.e., fluxes), and whiskers of tin.

Many lead-free solders are based on Sn–Ag–Cu formulations, with Sn–3.5Ag, Sn–0.7Cu, and Sn–3.8Ag–0.7Cu widely in use because of their good mechanical and wetting properties. In 3.5% sodium chloride solution, lead-free solders show an improved corrosion resistance compared with Sn–Pb solder because of lower active currents and lower passive current densities and that the Sn–Ag material was the most resistant.<sup>56</sup> The contact resistance and fretting corrosion resistance of lead-free solders were measured as a function of time.<sup>57</sup> In this case, the contact resistance of the conventional eutectic solder fell more quickly than the lead-free solder; however, the fretting corrosion resistance of Sn–Ag materials was generally improved. The lead-free solders performed significantly better than did the lead-containing solders after steam aging at 93 °C, 100% RH and after mixed flowing gas testing (in 200 ppb NO<sub>2</sub>, 10 ppb H<sub>2</sub>S, 10 ppb Cl<sub>2</sub>) at 30 °C and 70% RH.

There is, therefore, good evidence that the general and fretting corrosion behavior, and consequent contact resistance changes with time, of lead-free solders is at least as good as, and often better than, traditional tin-lead eutectic solders. However, lead-free solders have a greatly increased tendency for the formation of thin filamentary whiskers of tin, which may lead to

failure by short-circuit. Tin whisker formation has been known for many years and was originally thought to be driven primarily by electromigration between two contacts or conductive tracks.<sup>58,59</sup> More recently, however, it has become clear that most whisker growth is a process driven by relief of stresses<sup>60</sup> (i.e., from plating or from contact forces), although electromigration may play a role in more extreme conditions.<sup>61</sup>

### 3.12.4.4 Bearing Metals

There are several classes of tin-containing bearing alloys for use in lubricating conditions: high-tin alloys (substantially lead-free), bearing alloys containing increasing amounts of lead, and aluminum tin alloys; each class may have minor elements (e.g., antimony, indium) added to promote, for example, intermetallic formation. The corrosion of tin-rich white metal bearings is rare, and consequently, detailed studies of the phenomenon are not extensive in the literature. High-tin alloys are relatively resistant to corrosion in the organic acids that tend to be formed during the degradation of lubricating fluids and the tin salts that form have antioxidant capability. Where corrosion of tin-rich bearings has occurred, it is invariably associated with water ingress.<sup>62</sup> For example, 500 ppm water has been shown to be sufficient to cause corrosion, especially in conjunction with chlorine-based high-pressure additives in the oil.<sup>63</sup>

When free access of salt water to a bearing is possible, the tin-lead ‘Babbitt’ alloys are not suitable, since they are cathodic to steel shafts. For underwater bearings, alloys with 70% Sn, 1.5% Cu, and the balance Zn, are traditionally used; the possible dissolution of zinc gives cathodic protection to the shaft, although the more easily replaced bearing suffers some corrosion.

### Glossary

**White rust** A porous layer of zinc oxide and hydroxide build up on zinc coatings after storage in poorly ventilated conditions.

**ISO CORRAG** International organization for standardization-collaborative atmospheric exposure program

**SHG** Special high grade (reference to zinc purity)

**ZA** Zinc aluminum

### Abbreviations

**ASTM** American Society for Testing and Materials

**BISRA** British Iron and Steel Research Association

**GOB** Good ordinary brand (reference to zinc purity)

**HG** High grade (reference to zinc purity)

**ISO** International organization for standardization

### 3.13.1 Introduction

#### 3.13.1.1 History

Despite its frequent occurrence with lead, zinc (boiling point 907 °C) was not known to the ancient world as it was generally lost during smelting by evaporation. Thus, the earliest reports of metallic zinc date only from the fifteenth century in China, while in

Europe zinc was not recognized as a separate element until the eighteenth century when small smelting works were first set up for its production. Its earliest use was in alloying, especially with copper (to produce brass), although its compounds were also used for medicinal purposes (e.g., calamine,  $\text{ZnCO}_3$ ) and as pigments. Significant European production of zinc commenced from the early eighteenth century. Prior to the discovery of significant lead–zinc sulfide mineralization (e.g., at Broken Hill in Australia), the principal ore source was zinc carbonate (calamine) found throughout Europe and also in the United Kingdom. Final stimulus for the mass production of zinc did not arrive until the dual discoveries of galvanizing for steel and zinc sheet production in the mid-nineteenth century.

### 3.13.1.2 Production and Usage

The excellent resistance of zinc to corrosion under natural conditions is largely responsible for the many and varied applications of the metal. In fact, half of the world consumption of zinc is in the form of coatings for the protection of steel from corrosion. Zinc is produced and sold according to standard specifications. Three principal grades are recognized by international standards organizations such as ISO, where the zinc specifications are set forth in ISO 752, and the various national standards organizations such as ASTM (Standard Specification B6). The great majority of zinc sold today is made by the electrolytic process, to a purity of 99.99% zinc, and is commonly referred to as special high grade (SHG) zinc. A lower purity grade termed high grade (HG) has a minimum zinc content of 99.9%; the old standard grade, containing 98.0% minimum zinc, is commonly termed Prime Western or good ordinary brand (GOB) zinc. Common impurities in all three grades are lead, cadmium, and iron. Grades with higher purities than SHG are available but are not referred to in the national or international standard specifications.

Zinc in coatings used to protect steel articles coated after fabrication is generally SHG or GOB zinc, although coatings with minor additions of nickel and tin (added during the galvanizing process) can be used to control the reactivity of the steel. Zinc coatings used in continuous coating of sheet and wire are almost always SHG alloyed with aluminum at various levels around 0.15%, 5%, and 55% Al. Additions of magnesium up to 3% can also be made. Further details on zinc coatings and their performance are described elsewhere.

Zinc casting alloys account for about 20% of annual zinc usage. These alloys are commonly alloyed with 4% aluminum to improve castability and strength. Smaller quantities of zinc alloys containing 8, 12, or 27% aluminum, termed ZA alloys, are also utilized. Die castings can be made readily on account of the low melting points and the good flow properties of zinc alloys. Continuous casting is also used, mainly for production of hollow cylinders for bearing materials but also as stock for machining of zinc shapes.

Another 6% of zinc production is sold in semi-manufactured form including rolled zinc roofing, anodes, and dry cell battery cans. Its malleability and ductility make it possible to produce zinc in sheet, strip, and plate form by rolling and as rod and wire by extrusion. Rolled zinc in sheet and strip form is a well-established roofing material, particularly in parts of France and northern Europe. A small amount of copper, up to 1.5%, is added to these alloys to improve creep strength. Brass (discussed in the section on copper alloys) and zinc chemicals (chiefly oxide) make up the balance of major zinc uses.

### 3.13.2 Physical and Mechanical Properties

The bluish-white form of the unalloyed metal is familiar. It is moderately hard and quite malleable at normal temperatures. The tensile strength and impact resistance of the unalloyed metal, although greater than that of tin or lead, are low, so unalloyed zinc is not to be regarded as a structural metal. The main consequence of using unalloyed zinc in applications subject to prolonged loading is the occurrence of creep deformation. Although brittle at room temperature, pure zinc can be rolled and otherwise formed at about 100 °C.

The physical and mechanical properties of pure zinc are given in [Table 1](#). A detailed description of the physical and mechanical properties of zinc alloys for cast and wrought zinc products is given in [Table 1](#).<sup>1</sup>

Factors influencing the physical and mechanical properties of zinc pressure diecasting alloys are their composition and the cooling rate after casting. Modern zinc pressure diecastings are made with wall thickness between about 0.75 and 3 mm. Such thin sections, coupled with the high cooling rate of the metal die, results in very uniform microstructures. A very fine distribution of zinc-rich and aluminum rich phases is observed regardless of composition.

**Table 1** Mechanical and physical properties of pure zinc

<i>Property</i>	
Tensile strength (cast)	28 MN m <sup>-2</sup> (4000 psi)
(rolled – with grain)	
(99.95% zinc soft temper)	126 MN m <sup>-2</sup> (18 000 psi)

Gravity cast zinc–aluminum alloys cool at slower rates, allowing coarser microstructures to be produced. However, the average grain size is still of the order of 1 μm, meaning that galvanic effects between the zinc-rich and aluminum-rich constituents of the microstructure are not observed in practice.

Rolled zinc for architecture and other outdoor uses is generally on the basis of the use of zinc–copper–titanium alloys, where the maximum levels of copper and titanium are 1.5% and 0.15%, respectively. However, the relatively high creep strength attainable in this family of alloys can be realized only if the correct mechanical and thermal treatments have been used. A fine-grained, uniformly corroding sheet product can be obtained.

### 3.13.3 Corrosion Properties

Both zinc and zinc alloys have excellent resistance to corrosion in the atmosphere and in most natural waters, particularly if the waters are scale-forming. The property which gives zinc this valuable corrosion resistance is its ability to form a protective layer consisting of zinc oxide and hydroxide, or of various

basic salts, depending on the nature of the environment. When the protective layers have formed and completely covered the surface of the metal, the corrosion proceeds at a greatly reduced rate.

#### 3.13.3.1 Protective Layers on Zinc

In dry air, a film of zinc oxide is initially formed by the influence of atmospheric oxygen, but this is soon converted to zinc hydroxide, basic zinc carbonate, and other basic salts by water, carbon dioxide and chemical impurities present in the atmosphere. It is possible to form many zinc compounds during the process of corrosion of zinc, particularly in tap water. In atmospheric exposures also, the reactions are complex, but a simplified summary is given in [Table 2](#).

Below about 200 °C, the initially formed thin film grows very slowly, is invisible and very adherent. This initially formed layer influences the corrosion resistance of the zinc throughout its life. If the film becomes too thick, it is liable to break away or become porous, when, of course, it ceases to provide protection. Moreover, zinc corrosion products occupy a larger volume than the zinc from which they originated and, as the layer thickens, strains are set up which lead to the production of fissures and cracks.

Factors influencing the formation of protective layers are the local pH and the presence of acidic pollutants in the environment. Zinc forms an amphoteric oxide and therefore, the formation of protective layers is slowed by both acidic and alkaline conditions.

Vernon<sup>2</sup> claims that in outdoor atmospheres the corrosion products consist largely of zinc oxide, hydroxide and combined water, but they also contain zinc sulfide, zinc sulfate, and zinc carbonate. The corrosion products can be complex and the manner in which they develop into passive films is described in great detail by Zhang.<sup>3</sup> [Figure 1](#) shows how the corrosion rate of zinc varies with the pH<sup>4</sup> and it will be seen from this that the attack is most severe at pH values below 6 and above 12.5, while within this range the corrosion is very slow. The actual rates of corrosion shown in [Figure 1](#) are not of direct relevance, being from aqueous solutions; however the general shape of the curve has been confirmed for many environments.<sup>5</sup>

The electrochemical properties of zinc also have a large bearing on its corrosion behavior. Zinc is more active than the hydrogen equilibrium potential and most other metals commonly encountered, except magnesium and aluminum, but including those found

**Table 2** Zinc corrosion reactions in different atmospheres (schematic)

Type of atmosphere	Attacking substances	Corrosion products		
		composition	Relative solubility in water	Corrosion rate
Rural	$O_2 + H_2O + CO_2$	$ZnO \rightarrow Zn(OH)_2$ $\rightarrow 2ZnCO_3 \cdot 3Zn(OH)_2$	Very low	Very low
Marine	$O_2 + H_2O + CO_2 +$	$ZnO \rightarrow Zn(OH)_2$ $\rightarrow 2ZnCO_3 \cdot 3Zn(OH)_2 \rightarrow$	Moderate	Low
	+ Cl	$\left\{ \begin{array}{l} ZnCl_2 \cdot 4Zn(OH)_2 \\ ZnCl_2 \cdot 6Zn(OH)_2 \end{array} \right\} + \left\{ \begin{array}{l} Zn_3OCl_4 \\ Zn_4OCl_6 \end{array} \right\}$		
Urban and Industrial	$O_2 + H_2O +$ + $CO_2 +$ + $SO_2$	$ZnO \rightarrow Zn(OH)_2$ $\rightarrow 2ZnCO_3 \cdot 3Zn(OH)_2 \rightarrow$ $\rightarrow ZnS + ZnSO_3 + ZnSO_4$	Good	High

$CO_2$  has been included as an attacking substance because it participates in the formation of corrosion products. However,  $CO_2$  is also necessary to form stable films.

Source: Thomas, R. *Rust Prevention by Hot Dip Galvanizing*; Nordic Galv. Assoc.: Stockholm, Sweden, 1980; 32 pp.

**Figure 1** Effect of pH on the rate of corrosion of zinc: (a) rapid corrosion, (b) stable film – low corrosion rate, (c) rapid corrosion. Reproduced from Roetheli, B. E., Cox, G. L.; Littreal, W. B. *Metals and Alloys* **1932**, 3, 73.

in the less pure forms of zinc. This means that when zinc is in contact with these metals sacrificial electrochemical action (galvanic corrosion) can take place, with zinc forming the anode. Contact with other metals and impurities can therefore cause zinc to corrode rapidly and it is important to avoid intermetallic contacts with metals such as copper, tin, iron or nickel,

under immersion in water. On the other hand, the overvoltage for hydrogen evolution on zinc is high, and this can, in some circumstances, lead to a reduction in the corrosion rate, although under normal atmospheric conditions oxygen is generally present in sufficient concentration to act as a cathode reactant.

The severity of bimetallic corrosion is dependent on the ratio of the areas of metals in contact, the duration of wetness, and the conductivity of the electrolyte. For example, other things being equal, seawater, a highly conducting solution, gives rise to more severe bimetallic corrosion than most fresh waters that are of lower conductivity. A film of moisture condensed from the air or rainwater can dissolve contaminants and provide conditions conducive to bimetallic corrosion. Moreover, contaminants already present on the metal surface, such as fingerprints or residues of processing solutions, may absorb moisture from the atmosphere that, although humid, has not actually reached the dew point.

### 3.13.3.2 Atmospheric Corrosion

#### 3.13.3.2.1 General properties

In dry air, the stability of zinc is remarkable and is conferred by the development of insoluble basic carbonate films after the initially formed oxide layer is exposed to the usual carbon dioxide-containing atmosphere. Once this protective layer of zinc is complete, further attack is negligible. Even under normal urban conditions, such as those in London, zinc sheet, 0.8 mm thick, has been found to have an

effective life of 40 years or more when used as a roof covering and no repair has been needed except for mechanical damage.

Two factors accelerate zinc corrosion in the atmosphere: the duration and frequency of moisture contact and the extent of atmospheric pollution. When moisture is present the initial corrosion product is zinc hydroxide, which is then converted by the action of carbon dioxide to a basic zinc carbonate of composition similar to  $\text{ZnCO}_3 \cdot 3\text{Zn(OH)}_2$ .<sup>6</sup> In very damp conditions, unprotected zinc sometimes forms a loose and more conspicuous form of corrosion product known as 'wet storage stain' or 'white rust.'

Industrial atmospheres usually accelerate the corrosion of zinc. When heavy mists and dews occur in these atmospheres, they are contaminated with considerable amounts of acidic substances such as sulfur dioxide and the film of moisture covering the metal can be quite acidic and can have a pH as low as 3. The formation of basic protective films is prevented when zinc is attacked by acidic moisture. Under these conditions the zinc is dissolved but, as the corrosion proceeds, the pH rises, and when it has reached a sufficiently high level basic salts are once more formed and provide further protection for the metal. These usually contain the basic carbonate but may sometimes contain a basic sulfate. As soon as the pH of the moisture film falls again, owing to the dissolution of acidic gases, the protective film dissolves and renewed attack on the metal occurs. Hudson and Stanners<sup>7</sup> conducted tests at various locations in order to determine the effect of atmospheric pollution on the rate of corrosion of steel and zinc. Their figures for zinc are given in Table 3 and clearly show the effect which industrial contamination has on the corrosion rate. The effect can vary with the direction of

the prevailing wind or the ease with which deposits can remain on the surface. Goodwin<sup>8</sup> reported that in acidic atmospheres the increase in corrosion is principally caused by dry deposition of sulfur dioxide and to a lesser extent by acid rain.

In areas near the sea coast, the rates of corrosion may be increased somewhat by the sea spray containing soluble chlorides, but the rates are still much lower than those prevailing in heavily polluted industrial areas. The white corrosion product which is sometimes found under these conditions probably consists of the basic chloride  $4\text{Zn(OH)}_2 \cdot \text{ZnCl}_2$ .<sup>6</sup> Chlorides have far less effect than sulfur compounds on the corrosion rate of zinc, but removal of salt deposits by washing is highly beneficial. The effect of chlorides is most harmful when it is combined with sulfurous contamination such as in coastal industrial areas. The effect of sea spray is very different in temperate and tropical areas, in addition to any temperature or humidity effects. Temperate seawater and spray contain higher portions of magnesium salts than those in tropical conditions; these salts help inhibit the corrosion of zinc.

Anderson,<sup>9</sup> reporting on a series of 20-year exposure tests carried out by the ASTM, quotes the average rates of corrosion for various types of environment which are given in Table 4.

These results clearly demonstrate; (a) the effect of moisture in increasing the corrosion rate six times in the rural areas compared with the arid areas, and (b) the considerable increase of attack in the industrial areas. Anderson considers that the principal features that control the rate of corrosion of zinc are; (a) the frequency of rainfall and dew fall, (b) the acidity of the atmosphere, and (c) the rate of drying. In situations where the drying of zinc is retarded, corrosion is found to be most severe, for example,

**Table 3** Atmospheric corrosion of zinc in various parts of the United Kingdom

Site	Degree of pollution	Standard pollution <sup>a</sup>	Corrosion rate (mm year <sup>-1</sup> )

the bottom strand of a galvanized wire fence, which is shielded from the sun by grass and weeds.

Ambler<sup>10</sup> has attempted to find a relationship between the corrosion of zinc and iron and atmospheric salinity in the United Kingdom. This followed previous tests in Nigeria,<sup>11</sup> when it was concluded that the governing factor in the corrosion of steel and zinc was airborne salt and that there was a relationship between corrosion and the distance from the sea. In the United Kingdom, however, no such relationship was found to exist and the governing factor in the corrosion of zinc in the atmosphere is confirmed to be the amount of sulfur dioxide pollution.

Environmental concerns have led to studies that have measured the release rate of zinc from rolled zinc sheet during atmospheric exposure. These sheets were exposed either in new conditions or after prior outdoor exposure for durations up to 62 years, at three locations, Stockholm (urban), Olen, Belgium (industrial), and Hoboken, Belgium (urban-highly industrial), for 1 year. Figure 2 shows both the corrosion rates and the zinc runoff rates as a function of atmospheric sulfur dioxide concentration. The runoff

rate is observed to be considerably lower than the corrosion rate, and the corrosion rate was independent of the age of the preweathered panel, depending only upon the sulfur dioxide concentration of the atmosphere.<sup>12</sup> After release from the panel, most dissolved zinc quickly combines with the cations in the soil or water, leaving very little available for interaction with living forms.<sup>13</sup>

### 3.13.3.2 White rust

When condensation occurs on a fresh zinc surface, as may easily happen during storage in an environment with restricted circulation in which the temperature varies periodically, zinc is generally attacked by the oxygen dissolved in the water, owing to differential aeration between the edges and the centers of the drops. In this form of corrosion, a porous layer of zinc oxide and zinc hydroxide builds up. If the supply of air to the surface is restricted, insufficient carbon dioxide is supplied for the normal formation of a protective zinc carbonate layer. The resulting corrosion product, termed white rust or wet storage stain, is voluminous and porous, and adheres only loosely to the zinc surface. Consequently, it does not protect the zinc against corrosion, which can therefore proceed so long as there is moisture on the zinc surface.

This type of corrosion can take place on any new surface of zinc and is best prevented by storing the metal in a dry, airy place until a protective layer has been formed. Zinc, which has been properly aged in this way, is safe against white-rust formation. Various methods are employed to prevent white rust. Passivation treatments (e.g., chromate or phosphate) are widely used for zinc-plated articles and for galvanized sheet, and occasionally for zinc die castings. Fatty substances, such as oils or lanolin, are sometimes used to protect larger items. Light build-up of white rust can be removed by swabbing with dilute ammonia solution, for example: 19 ml ammonia, 6 g ammonium chloride, 6 g ammonium carbonate, and 71 ml tap water. The area should be well-ventilated and protective goggles should be worn by the operator.

### 3.13.3.3 Aqueous Corrosion

#### 3.13.3.3.1 Corrosion of zinc in natural waters

Fundamentally, the rate of zinc corrosion depends upon the type, quantity and mode of corrosion products. When zinc is immersed in distilled water containing dissolved oxygen, a protective film, probably

**Table 4** Further examples of atmospheric corrosion rates for zinc

**Figure 2** Experimental values and regressions (lines) for corrosion rates (squares) and runoff rates (circles) of zinc. Reproduced from Odneval Wallinder, I., et al. *Corros. Sci.* **1988**, 40(11), 1977–1982.

consisting of zinc hydroxide, is slowly formed and this extends over nearly the whole surface. At certain points the metal seems to remain uncovered and local attack continues, resulting in pitting. This may be quite serious and can lead to the rapid penetration of a zinc sheet. The attack does not spread over the whole surface of the zinc but is confined to these small local areas, although similar pits are liable to appear at points in a vertical line directly below the seat of the original corrosion. It has been suggested that the areas attacked occur where particles of corrosion product have fallen and are resting on the surface, shielding it from oxygen. The point thus shielded becomes anodic and suffers corrosion. If oxygen replenishment is made uniform over the whole surface, for example, by 'whirling'<sup>9</sup> a zinc plate, pitting is avoided and the protective film of zinc hydroxide is found over the entire surface. However, too much agitation can sweep away corrosion products before they can become protective. The corrosion rate of zinc in distilled water ranges between 15 and 150  $\mu\text{m year}^{-1}$  and depends strongly on the amount of dissolved oxygen and carbon dioxide.<sup>3</sup> Corrosion data are shown in Table 5.

The factors affecting zinc corrosion in distilled water – oxygen, carbon dioxide content, and agitation – also affect corrosion of zinc by natural waters.

**Table 5** Effect of oxygen on the corrosion of zinc in distilled water

Natural waters all contain dissolved salts to a certain extent and these tend to form a scale on the surface of the metal. As such scales have a protective affect it is to be expected that corrosion will be less severe in natural, particularly hard, water. This is in fact true and it is often found that distilled water is more corrosive than natural waters. Whether the water is scale forming or not is determined by calculating the Langlier saturation index, a relationship involving concentrations of carbon dioxide, calcium bicarbonate and calcium carbonate together with pH described elsewhere in this handbook. The effect of free carbon dioxide in a hard tap water and in equal mixtures of hard water and low conductivity water is shown in Figure 3.

The effect of pH on the corrosion of zinc has already been mentioned. In the range of pH values from 5.5 to 12, zinc is quite stable and as most natural waters come within this range, little difficulty is encountered in respect of pH. If the pH is below the value at which the water is in equilibrium with calcium carbonate, the calcium carbonate will tend to dissolve rather than form a scale. The same effect is produced in the presence of considerable amounts of carbon dioxide, which also favors the dissolution of

**Figure 3** Effect of free carbon dioxide on the corrosion of zinc in different waters: (■) conductivity water; (○) hard water; (●) equal mixture of hard and conductivity water. calcium carbonate. In addition, it is important to note that small amounts of metallic impurities (particularly copper) in the water can cause quite severe corrosion and as little as 0.05 ppm of copper in a domestic water system can be a source of considerable trouble with galvanized tanks and pipes. The copper deposits as small cathodic particles on the zinc surface and thereby accelerates localized pitting corrosion.

### 3.13.3.3.2 Corrosion in seawater

Seawater contains considerable amounts of soluble salts, particularly sodium chloride, which is present in concentrations from 1 to 25%. The North Sea, for example, contains about 3% sodium chloride, 0.47% magnesium sulfate, 0.2% magnesium chloride, and 0.1% calcium chloride. The carbon dioxide content is about 0.0005–0.01% and the pH is between 7.6 and 8.1. The high chloride content would tend to increase the rate of corrosion and this usually takes the form of pitting under these conditions. The corrosive influence of the chloride ions is, however, inhibited by the presence of magnesium and calcium ions by virtue of the formation of a protective layer of magnesium and calcium salts (calcareous scale). Typical corrosion rates of zinc range from  $25 \mu\text{m year}^{-1}$  in the tropics to half that in temperate seas such as the North Atlantic. In tidal areas, where zinc surfaces are immersed twice daily, or areas washed by waves, the corrosion rate is typically twice that of completely immersed zinc.

The effect of the magnesium salts has been clearly demonstrated by Schikorr.<sup>14</sup> Zinc immersed in a solution containing  $30 \text{ g dm}^{-3}$  of sodium chloride showed a weight loss of  $198 \text{ g m}^{-2}$  after 14 days. When the solution contained in addition  $12 \text{ g dm}^{-3}$  of magnesium chloride, the loss in weight was only  $4 \text{ g m}^{-2}$  after the same period. Artificial seawater was also tested and gave a weight loss of  $5 \text{ g m}^{-2}$ .

Zinc roofs are quite satisfactory at the coast, where they receive a large amount of saltwater spray, and many British piers have been covered with sheet zinc, which has lasted 50 years and more. Most of the zinc actually immersed in seawater is in the form of zinc coatings, the behavior of which is discussed elsewhere. Experience with these coatings has proved the value of zinc in seawater compared with many other metals in this environment.<sup>15</sup>

### 3.13.3.3.3 The effect of temperature

It is found that temperature has a marked effect on the rate at which zinc corrodes in water. The

**Figure 4** Effect of temperature on the corrosion rate of zinc sheet in distilled water. Reproduced from Maconachie, J. E. *Trans. Electrochem. Soc.* **1934**, 66, 213–221.

corrosion rate in distilled water reaches a maximum in the temperature range 65–75 °C, **Figure 4**.

This variation in the corrosion rate with temperature is attributed to changes in the nature of the protective film. At lower temperatures the film is found to be very adherent and gelatinous, while at temperatures around 50 °C it becomes distinctly granular in character and much less adherent. Above 75 °C it again tends to become more adherent and assumes a very compact and dense form. It is believed that the granular coating formed at temperatures around 70 °C is more porous than the others and permits greater access of the dissolved oxygen to the metal. Casting alloys are considerably more corrosion resistant in water than pure zinc because they contain aluminum. **Figure 5** shows the effect of temperature on corrosion of three casting alloys with 8%, 12%, and 27% aluminum. The temperature where maximum corrosion rates are observed is 60 °C.

### 3.13.3.4 Soil Corrosion

The factors influencing the corrosion of metals in soil are more numerous than those prevailing in air or water and the electrochemical effects are more pronounced. Moreover, soils vary widely in their composition and

**Figure 5** Effect of temperature on the corrosion rate of ZA alloys in tap water, 30–45 day tests. Reproduced from Belisle, S.; Dufresne, R. In *International Symposium on Zinc–Aluminum (ZA) Casting Alloys*, Toronto, Canada; Canadian Institute of Mining and Metallurgy: Montreal, 1987; pp 109–126.

behavior even over very short distances. Many chemical elements are present in soils, but the ones influencing zinc corrosion behavior are those which are soluble in water, notably base-forming elements such as sodium, potassium, calcium and magnesium. Acid-forming groups such as carbonate, bicarbonate, chloride, nitrate, and sulfate are equally important to consider. The electrical resistivity of soils also strongly influences zinc corrosion rates and is determined by the nature and concentration of the ions formed by chemical salts dissolved in the soil moisture. Moreover, zinc corrosion rates are influenced by physical properties of soils that determine their permeability to air and water. Because of the wide variety of possible soil conditions, it is difficult to obtain reliable data. It is evident, however, that zinc has considerable resistance to corrosion when buried and the severest attack is caused by soils, which are acidic or contain large amounts of soluble salts. A general guideline is that a  $600 \text{ g m}^{-2}$  galvanized coating on steel will provide protection for 10–20 years in inorganic oxidizing soils but half of this time in inorganic reducing soils.

In tests carried out by the National Bureau of Standards in the United States (now the National Institute of Standards and Technology)<sup>16</sup> specimens of copper alloys, lead, zinc, and zinc alloys were buried at a number of different sites for periods varying from 11 to 14 years. The soils tested covered a pH range from 2.6 to 9.4 and resistivities ranged

from 60 to  $17\,800 \Omega \text{ cm}$ . The weight losses and maximum depths of pitting were recorded and the results indicated that the most severe corrosion occurred in soils of poor aeration having high acid and soluble-salt contents. Details are shown in [Table 6](#).

Although there was no significant difference in weight loss between rolled zinc and zinc alloys, the maximum penetration of the alloys definitely appeared to be greater than that of rolled zinc. BISRA tests on galvanized steel pipe buried for five years at five different sites are described by Hudson and Acock.<sup>17</sup> The galvanized pipes resisted corrosion rather better than steel at all sites. Galvanized pipes of small diameter are frequently used to provide underground water services in farms and similar establishments, and little trouble is experienced.

### 3.13.3.5 Corrosion Resistance of Zinc in Chemical Environments

#### 3.13.3.5.1 Acids and alkalis

Zinc dissolves in liquids whose pH is below about 5 and above 12.5. Many acids have pH levels below 5 and therefore will attack zinc, while only the stronger solutions of most alkalis would cause any corrosion. Zinc dissolves in caustic soda solution to form zincate ions, that is,  $\text{ZnO}_2^{2-}$ . Many other factors including agitation, aeration, temperature, polarization, and in some cases the presence of inhibitors may considerably influence the corrosion rate of zinc.

Owing to the high overpotential for hydrogen evolution pure zinc is attacked only very slowly by dilute sulfuric and hydrochloric acids, but impure zinc dissolves quite readily, evolving hydrogen. Thus, when ordinary commercial zinc is placed in a dilute acid it immediately starts to corrode, at first relatively slowly. As corrosion proceeds the impurities present are reprecipitated as a black metallic sponge which may further accelerate the reaction owing to the increased surface area of low overpotential cathodic sites, for example, copper. Some metallic impurities, notably aluminum, retard the corrosion of zinc by acids. This is due to the production of highly protective films. Other metals, such as tin and lead, retard the corrosion initially but after a few hours they are deposited as a metallic sponge, resulting in corrosion as rapid as with ordinary zinc.

Zinc is widely used in contact with many milder chemicals such as detergents and agricultural chemicals. In most cases, zinc or zinc-coated steel comes in contact with these chemicals during handling, packaging and storage.

### 3.13.3.5.2 Salt solutions

When a zinc sheet is immersed in a solution of a salt, such as potassium chloride or potassium sulfate, corrosion usually starts at a number of points on the surface of the metal, probably where there are defects or impurities present. From these it spreads downwards in streams, if the plate is vertical. Corrosion will start at a scratch or abrasion made on the surface but it is observed that it does not necessarily occur at all such places. In the case of potassium chloride (or sodium chloride) the corrosion spreads downwards and outwards to cover a parabolic area. Evans<sup>18</sup> explains this in terms of the dissolution of the protective layer of zinc oxide by zinc chloride to form a basic zinc chloride, which remains in solution.

Feitknecht<sup>19</sup> has examined the corrosion products of zinc in sodium chloride solutions in detail. The compound on the inactive areas was found to be mainly zinc oxide. When the concentration of sodium chloride was greater than 0.1 M, basic zinc chlorides were found on the corroded parts. At lower concentrations a loose powdery form of a crystalline zinc hydroxide appeared. A close examination of the corroded areas revealed craters, which appeared to contain alternate layers and concentric rings of basic chlorides and hydroxides. Two basic zinc chlorides were identified, namely  $6\text{Zn}(\text{OH})_2 \cdot \text{ZnCl}_2$  and  $4\text{Zn}(\text{OH})_2 \cdot \text{ZnCl}_2$ . These basic salts and the crystalline zinc hydroxides were found to have layer structures similar in general to the layer structure attributed to the basic zinc carbonate which forms dense adherent films and appears to play such an important role in the corrosion resistance of zinc against the atmosphere. The presence of different reaction products in the actual corroded areas leads to the view that, in addition to action between the major anodic and cathodic areas as a whole, there is also a local interaction between smaller anodic and cathodic elements.

### 3.13.3.5.3 Organic chemicals

Most organic liquids, other than the stronger acids, attack zinc only slowly. Zinc is therefore suitable for storage tanks for liquid hydrocarbons such as motor fuels, for phenols and for trichlorethylene degreasers. Particular care must be taken to exclude moisture, because corrosion at the interface between moisture and hydrocarbon fuels may be considerable. Zinc or zinc-coated vessels are not recommended for use in contact with acid foodstuffs, but are regularly used for dry foods. Zinc is essential in the human diet; the typical recommended daily allowance is 15 mg.

### 3.13.3.6 Cathodic Protection by Zinc Anodes

Zinc should give a potential of  $-1.05\text{ V}$  versus  $\text{Cu}/\text{CuSO}_4$  and should have a driving potential of about  $-0.25\text{ V}$  with respect to cathodically protected steel. Zinc is therefore sufficiently negative to act as a sacrificial anode and its first use for such purposes was on the copper-sheathed hulls of warships more than a century ago. The first attempts to fit zinc anodes to steel hulls, however, were a complete failure, for the sole reason that it had not been realized that the purity of the zinc was of paramount importance. The presence of even small amounts of certain impurities leads to the formation of dense adherent films, which cause the anodes to become inactive.

The major harmful impurity is iron and by keeping the iron content to less than 15 ppm it became possible to produce perfectly satisfactory anodes of zinc.<sup>20,21</sup> Alternatively the effect of the iron can be neutralized by alloying the zinc with certain metals, among which aluminum and silicon or cadmium have been found to be particularly effective. However such alloyed anodes are susceptible to intercrystalline corrosion particularly above  $50^\circ\text{C}$  and for such temperatures the purer anodes are preferable. The presence of cadmium causes the corrosion product to fall away evenly, leaving an active surface.

Zinc alloy anodes are generally very efficient, owing to their nonpolarizing characteristics and to the absence of parasitic reactions when buried or immersed. Therefore, as zinc's 'self-corrosion' is very small, the anode's high efficiency of 85–95% holds throughout the current-density range, whereas the efficiency of magnesium, about 50–55% at high current densities, may fall to only 30% at low current densities. The use of these zinc alloys for reference electrodes to monitor some hull-protection schemes or as permanent reference cells located along pipelines, underlines their nonpolarizing characteristics. The electrochemical equivalent of zinc indicates that  $10.5\text{ kg}$  should give  $1\text{ A year}^{-1}$ , but in practice this amount of charge is given by about  $11\text{--}12\text{ kg}$  of zinc compared with  $7.7\text{--}9\text{ kg}$  of magnesium. As the cost of zinc is relatively low, zinc anodes are found to be very economical. Moreover, as zinc is fairly dense, the volume consumption is about three times lower than that for magnesium and the dimensions of the zinc anode are correspondingly smaller.

The driving potential of zinc to cathodically protected steel is  $200\text{--}250\text{ mV}$  and this is considerably lower than the  $700\text{ mV}$  given by magnesium. While

this value is ideal in seawater or other electrolytes of low resistivity, the use of zinc is not always practicable in environments of higher electrical resistance. For example, it is not likely to be of much use for protecting large underground systems in a high resistivity soil, but on the other hand it proves to be of value for smaller underground units, such as storage tanks, situated in soils of resistivity below about  $3000 \Omega \text{ cm}$ . Olive,<sup>22</sup> for instance, in the United States, discussed the application of zinc anodes for protecting underground equipment at gasoline filling stations. Larger installations, which employ a considerable number of zinc anodes, are the protective schemes for the steel gas mains in Houston and New Orleans.<sup>23</sup> Of a total of some 1200 galvanic anodes in New Orleans about 1000 are of zinc. This is a good example of a case where a system of zinc anodes can be used to protect a large underground installation under the right soil conditions. Zinc is used quite widely for the protection of bare service pipes of small diameter and is receiving increased acceptance for the protection of large-diameter coated pipes in built-up areas in order to minimize interference on adjacent mains. It is also used for protecting galvanized cold-water tanks.

Where the use of zinc anodes is practicable, the low driving potential is a great advantage as the resistance of the steel to be cathodically protected is the controlling resistance and the current output of the anode varies with the requirements of the cathode. Thus it can be said that zinc anodes are largely self-governing.

By far the largest use of zinc anodes is in seawater for the protection of ships' hulls and of North Sea pipelines and drilling rigs. The high conductivity of the seawater and the excellent natural resistance of zinc to corrosion make it very effective in this application. Many examples of trials with zinc anodes on ships can be quoted and the US Navy has done much work in this respect. One example is a paper by Carson,<sup>21</sup> describing zinc anodes attached directly to the hull, which were found to have a life of 8–10 years. This paper also gives the results of tests carried out at the Pacific Naval Laboratory, showing the effect of various impurities in the zinc. Carson looks into the economics of zinc alloy anodes and concludes that for small and medium hull sizes, for example,  $1400 \text{ m}^2$  wetted hull area, zinc alloy anodes are more economical than the most competitive alternative systems available and have the additional advantages of more even current distribution, minimum risk of paint-stripping, and maintenance-free

long life. For larger hull areas zinc alloy anodes are at least as economic as many alternative systems.

Zinc anodes are made in a variety of shapes and sizes, ranging in weight from 2.25 to 11 kg and in shape from cylindrical rods to rectangular bars. When used underground they are usually placed in a backfill, consisting of gypsum, sodium sulfate and clay, which may be added loose, shipped in a bag around the anode, or obtained in cast form.

The use of zinc anodes together with protection of steel by paint or polymer coatings has been found to confer great advantages of longevity. Even the best types of paint or polymer coatings are porous, so corrosion of the underlying metals must ultimately occur. This may take several years with the best coatings, but the corrosion ultimately destroys the adhesion between the metal and coating so that rapid deterioration takes place. The use of zinc anodes in conjunction with a protective coating greatly improves service life. The corrosion which undermines the coating is prevented and the coating remains firmly attached to give its maximum life. At the same time, the consumption of zinc is reduced dramatically, typically by a factor of 10, because much less steel is exposed and needs protection; a zinc consumption of less than  $1.2 \text{ kg A}^{-1} \text{ year}^{-1}$  (i.e., about  $0.12 \text{ kg year}^{-1} \text{ m}^{-2}$  of surface to be protected) is a reasonable estimate. The combination of coating and cathodic protection can therefore prove most economical.

### 3.13.3.7 Zinc–Aluminum (ZA) Casting Alloy Corrosion

#### 3.13.3.7.1 Behavior of the ZA alloys in aerated water from pH 2.0 to 13.0

As part of an International Lead Zinc Research Organization Programme, the corrosion behavior of the ZA casting alloys has been studied at the Noranda Research Center in Canada.<sup>24</sup> Air was bubbled continuously through distilled water flowing through the corrosion cells, its pH being controlled by additions of hydrochloric acid or sodium hydroxide. The temperature was  $22 \pm 2^\circ \text{C}$ . Pure zinc sheet was included for comparison. The results are on the basis of immersion times of 4–15 days and show that ZA27 undergoes little attack between pH 6 and 11.5, as does pure zinc. At pH 4.0 there was preferential attack of the decomposed  $\beta$ -phase, whereas at pH 12.8 there was selective dissolution of the aluminum-rich primary dendrites leaving a sponge-like surface. The samples were gravity cast plates.

### 3.13.3.7.2 Behavior of ZA alloys in neutral salt spray

The ASTM B 117 neutral salt spray test was used with pure zinc and the 4% aluminum diecasting alloy. They were observed to be corroded slightly more than ZA8 and ZA12 during up to 600 h exposure; after longer periods the difference diminished. ZA27 corroded at about one-third the rate of the other alloys, probably because attack occurs on the zinc rich matrix, while ZA27 contains a significantly larger amount of the aluminum-rich phase and behaves like the aluminum die-casting alloy 380 also included in the test.<sup>24</sup>

### 3.13.3.7.3 Behavior of the ZA alloys at a waste water plant

Gravity die cast ZA alloy test plates and 99.99% pure rolled zinc samples were exposed at a waste water treatment plant in Detroit, MI, USA. The results after one year are summarized in Table 7.<sup>20</sup> High corrosion rates were observed in these sedimentation tanks; by contrast steels with a zinc coating thickness of 85  $\mu\text{m}$  in similar locations in the United Kingdom were found to have substantial residual zinc after 7 years exposure.<sup>20</sup> The Michigan experience showed that the ZA alloys may be better than pure zinc in, for example, the secondary sedimentation tank, but additional protection should be provided unless there is satisfactory performance in a comparable water sample.

### 3.13.3.8 Intergranular Corrosion

Zinc of high purity is not susceptible to intergranular corrosion. However, this type of corrosion has been observed on zinc alloys in all common environments; the presence of alloying elements, aluminum in particular, is required to cause intergranular corrosion. With aluminum, intergranular corrosion is observed in the composition range 0.03–50% and is most severe at 0.2% because of the precipitation of aluminum-rich precipitates at zinc grain boundaries. The presence of other impurities, especially lead, cadmium and tin, greatly accelerates intergranular corrosion rates in zinc-aluminum alloys; however, maintaining the limits of these impurities within the SHG zinc specification prevents this. Heat treatment tends to increase grain boundary segregation in zinc casting alloys and therefore increases susceptibility to intergranular corrosion. Intergranular corrosion is most severe at higher temperatures and in moist, alkaline environments, especially above a pH level of 10.

**Table 7** Corrosion results from 1 year at Detroit, USA Wastewater Treatment Plant

<i>Exposure site</i>	<i>Sample</i>	<i>Corrosion rate (<math>\text{g m}^{-2} \text{year}^{-1}</math>)</i>
Atmospheric – Indoor		
Bar screen (high $\text{H}_2\text{S}$ concentration and humidity)	Zinc	1
	ZA8	2
	ZA12	1
	ZA27	1
Atmospheric – Outdoor		
Primary sedimentation tank (relatively high $\text{H}_2\text{S}$ and humidity)	Zinc	8–12
	ZA8	9
	ZA12	9
	ZA27	4
Secondary sedimentation tank (relatively high $\text{H}_2\text{S}$ and humidity)	Zinc	9
	ZA8	10
	ZA12	10
	ZA27	9
Immersed		
Primary sedimentation tank (wastewater with low $\text{O}_2$ containing phosphorus precipitants and coagulants)	Zinc	1239–1601
	ZA8	625
	ZA12	2181
	ZA27	1209
Secondary sedimentation tank (oxygenated wastewater containing microorganisms)	Zinc	857–1174
	ZA8	324
	ZA12	352
	ZA27	253

A corrosion rate of  $\text{g m}^{-2} \text{year}^{-1}$  corresponds to a uniform depth of penetration between 50 and 60  $\mu\text{m}$  for the ZA alloys. Visual examination of the immersed samples showed that ZA8 suffered moderate, uniform corrosion in both tanks. ZA12 showed extensive localized corrosion in the primary tank but slight uniform corrosion with localized corrosion at several spots in the secondary tank. ZA27 suffered extensive localized corrosion over most of the surface in the primary tank but only slight uniform corrosion with several very small pits dispersed all over the surface in the secondary tank.

### 3.13.4 Recent Developments

The most important recent development is the availability of computer-based prediction methods for zinc corrosion rates, particularly in atmospheric exposures. Traditionally, corrosion rates, and therefore service lives, have been estimated by using a generalized value for each type of atmosphere: rural, industrial, urban and marine. The certainty of prediction has recently been greatly improved by development of a prediction technique based on neural network modeling and assembly of a database relating zinc corrosion rate to the most important primary variables: annual average rainfall, temperature, relative humidity, sulfur dioxide deposition, sea salt deposition and time of

exposure<sup>25</sup>; 47 sets of data, representing different environments, were used to train the model. The correlation coefficient was greatly improved in comparison with past models; the average error of prediction is  $(36 \pm 13)\%$  at 95% confidence interval. The major source of error is believed to be factors other than the six that contribute to corrosion performance in this model. Nevertheless, the accuracy is improved in comparison to the ISO CORRAG model<sup>26,27</sup> and various published regression models.<sup>28–31</sup> The model is available at the internet site <http://www.galvininfo.com>

Alloys with higher contents of aluminum continue to grow in importance, especially for casting using metal or graphite moulds. Up to about 15% aluminum, the materials are non-sparking and can be used in mines. The corrosion behavior of the zinc–aluminum casting alloys can, for practical purposes, be considered as similar to that of pure zinc, even a factor of two in corrosion rate would be of little significance in a solid product. This is to be contrasted with both the behavior and significance of zinc–aluminum alloys when produced as coatings. In this latter case, the production process is designed to give inherently corrosion-resistant structures and only limited corrosion attack can be tolerated because the coating is thin. With castings, the only corrosion criterion is that harmful impurities such as lead, tin and cadmium, which could cause intercrystalline corrosion, should be below specified and low levels; the difference in levels of general corrosion is unlikely to affect the choice of alloy.

The general corrosion rates of zinc and zinc alloys in practice often have been shown to be much less than in simulated conditions; this is because many naturally occurring substances act as inhibitors. **Figure 1** is a good example of this. The diagram is valuable for the qualitative relationship among acid, neutral and alkaline conditions but, in practice, the corrosion rates are usually very much lower than that indicated by the pH because of the effect of other dissolved constituents and the barrier effect of corrosion products. Seawater around the British Isles is much less corrosive to zinc than tropical seawater.

It should be noted that the atmospheric corrosion data in **Table 3** are related to historic environments. Current use in the industrial areas listed with acidic pollution would show much lower corrosion rates as the corrosion of zinc in the atmosphere is essentially related to the SO<sub>2</sub> content (and the time of wetness) and in many countries the sulfurous pollution has been greatly reduced in the past 30 years. Zinc also benefits from rainwater washing to remove corrosive pollutants; therefore, although initial corrosion rates are usually not very

different on upper and lower surfaces, the latter tend, with time, to become encrusted with corrosion products and deposits, and these are not always protective.

### 3.15.1 Introduction

#### 3.15.1.1 Historical Information

Niobium was the first of this pair of elements to be discovered in 1801 when an English chemist, Charles Hatchett, analyzed a specimen of an unknown mineral that had been brought back from America to London.<sup>1</sup> He found evidence that it contained a new element and named it 'columbium' in homage to its original source. A year later, Anders Ekeberg of the University of Uppsala, analyzed a different mineral, this time originating from Ytterby in Sweden and isolated another previously unknown element.

He called his discovery 'tantalum' (after Tantalus, son of the Greek god Jupiter, who was sentenced to eternal frustration); isolating the element had obviously been an extremely difficult task.

Columbium and tantalum were assumed to be the same element for over 35 years until, in 1844, their individual valence states were uniquely identified; columbium had both +3 and +5 states while tantalum exhibited only a +5 state. In order to avoid misunderstanding, columbium was renamed 'niobium' (after Niobe, daughter of Tantalus) inadvertently creating over 100 years of dispute between metallurgists (who stuck to the name columbium) and chemists (who

preferred niobium). However, in 1949, the International Union of Pure and Applied Chemistry ruled that niobium was the official usage, although it is still sometimes referred to by its original name, especially in North America.

### 3.15.1.2 Occurrence and Production

Current primary sources of tantalum and niobium occur separately with the largest single source of tantalum in the world found in West Australia with additional resources in Canada, China, Brazil, and central Africa; it also occurs in small but significant quantities as a by-product of alluvial tin operations, for example, from southeast Asia.<sup>1</sup> The primary ore 'tantalite' is similar in composition to columbite and is an iron-manganese tantalum oxide ( $\text{Fe} + \text{MnTa}_2\text{O}_6$ ). Regarding niobium, the world's largest deposit is in Brazil with a pyrochlore mineralization ( $\text{Na} + \text{CaNb}_2\text{O}_6$ ); reserves here are sufficient to last over 400 years at current production rates. Columbite-tantalite ('coltan'), a mineral with a ratio of  $\text{Nb}_2\text{O}_5:\text{Ta}_2\text{O}_5$  ranging from 10:1 to 13:1, occurs in Brazil, Nigeria, and Australia as well as other countries in central Africa.

The extraction and refining of both the metals is determined by the need to separate the elements from each other. The final product is generally the oxide ( $\text{Ta}_2\text{O}_5$  or  $\text{Nb}_2\text{O}_5$ ) but the extraction and refining process involves mineral concentration, dissolution as complex fluorides and solvent extraction or liquid ion exchange. Tantalum and niobium industrial chemicals are generally produced from the oxides, or occasionally from an intermediary fluoride while the metals are derived from their corresponding precursors by thermal reduction using a reactive metal such as sodium or aluminum. The metallic powders can then be used directly for electronic applications (e.g., capacitors), which, in the case of tantalum, amounts to a significant volume (>50%) of the market. Metal powders are processed further under vacuum using electric-arc or

electron-beam melting into ingots for the production of pure material or alloys. Multiple remelting may be required to provide the desired level of metallic purity.

### 3.15.1.3 Physical Properties

Tantalum and niobium are immediately below vanadium in the same group of the periodic table and, hence, share many general properties. They are characterized by their exceptionally high melting points (respectively the fourth and sixth highest melting points of all the elements) and extremely high corrosion resistance due to very stable passive oxide films.<sup>2,3</sup> Like molybdenum and tungsten, they have body-centered cubic structures but, unlike them, their ductile to brittle transitions are well below room temperature ( $-150^\circ\text{C}$  for niobium,  $-200^\circ\text{C}$  for tantalum; both influenced by impurity content) and they have considerably lower strengths. Consequently, they have excellent ductility and can be easily formed and worked. However, both materials start to oxidize at significant rates above around  $200\text{--}300^\circ\text{C}$  and thus require protection at high temperatures, either by the use of coatings, or by keeping them in a protective atmosphere. Niobium has very similar properties, in general, to tantalum but has the advantage of being about half the density (i.e., twice the volume for the same mass) as well as cheaper. The physical properties of tantalum and niobium are similar to their adjacent colleagues in the periodic table, tungsten and molybdenum, respectively (Table 1).

### 3.15.1.4 Mechanical Properties and Alloying

Commercially pure annealed niobium and tantalum have relatively good mechanical properties with, depending on the level of impurities, strengths similar to, or somewhat less than, annealed austenitic stainless steel (Table 2). However, they have low

**Table 1** Selected physical properties of tantalum, niobium, molybdenum, and tantalum<sup>3</sup>

	<i>Tantalum (Ta)</i>	<i>Tungsten (W)</i>	<i>Niobium (Nb)</i>	<i>Molybdenum (Mo)</i>

Specific modulus (GPa g <sup>-1</sup> cm <sup>-3</sup> )	10.8	11.7	32.3	25

work-hardening rates (so, the yield stress does not increase to particularly high values after work hardening) and relatively low specific modulus. Despite being refractory metals, they have somewhat disappointing strengths at high temperatures compared with, for example, molybdenum and tungsten and, without alloying, the room temperature values are not maintained much beyond about 500–600 °C. This is not a practical constraint for aqueous corrosion applications. Both metals (and their alloys) are increasingly susceptible to oxidation above around 300 °C and must be protected in some way. Alloying (e.g., with tungsten, zirconium, etc.) increases the room- and high temperature strengths considerably but at the expense of ductility.

Both metals form a full range of solid solutions with each other resulting in properties that are generally intermediate between the two metals alone. The main commercial solid solution alloy is Ta–40Nb, which has mechanical and corrosion properties slightly lower than unalloyed tantalum but at lower cost. Tantalum may also be alloyed with tungsten ('Tantaloy'); Ta–2.5W, Ta–7.5W, and Ta–10W being the most common commercial alloys (Table 3). More complex systems are based on Ta–8W compositions; for example, T-111: Ta–8W–2Hf, and ASTAR 811C: Ta–8W–1Re–0.7Hf–0.025C (which is precipitation hardened). These alloys are designed principally for high strength maintained to reasonably high temperatures; oxidation protection is required and they are not generally used for corrosion applications. Other alloys include those with molybdenum and titanium (Ta–10Ti); the latter being useful for anode applications, as it is less dense (and cheaper) than unalloyed tantalum.

The mechanical properties and corrosion resistance of niobium are somewhat less than tantalum; however, the material is considerably cheaper. Many

**Table 3** Room temperature mechanical properties of some tantalum and niobium alloys<sup>4,5</sup>

Alloy	UTS (MPa)	YS (MPa)	Elongation (%)
Ta–2.5W	380	240	30
Ta–10W	620	480	30
Ta–40Nb	310	210	40
Nb–1Zr	195	125	20
Nb–10W–2.5Zr (Cb-752)	510	380	20
Nb–10Hf–1Ti (C103)	380	260	20
Nb–10Hf–10W–0.1Y (C129Y)	550	410	20

niobium alloys were developed to optimize their high temperature properties and these include Nb–10Hf–1Ti (C103), Nb–10W–2.5Zr (Cb-752), and Nb–10W–10Hf–0.1Y (C129Y); these alloys also require protection from high temperature oxidation when in use. However, unalloyed niobium is often specified for corrosion-resistant applications; where a higher strength material is required, Nb–1Zr can be substituted with little or no loss of corrosion resistance.

### 3.15.1.5 Fabrication

Owing to the high melting point and reactivity of tantalum and niobium with oxygen and nitrogen at high temperatures, which prevents conventional consolidation by melting and casting in air, the materials are normally vacuum-sintered, vacuum-arc melted, or electron-beam melted from compacted powder.<sup>4,5</sup> Vacuum sintering yields metal of fine grain, whereas electron-beam melting yields softer coarse-grained metal which requires cold forging prior to rolling. Metal produced by all three techniques will absorb considerable cold work (up to 90% reduction in area) before annealing is necessary; typically 1 h at 1200 °C

(in a vacuum or inert gas shielded furnace) gives full recrystallization. Both tantalum and niobium are weldable using tungsten-electrode inert gas (TIG), resistance, electron-beam (EB) and plasma-arc welding. However, welding is ideally carried out in an inert-gas chamber to avoid reaction with the atmosphere. Material thinner than 0.5 mm cannot readily be TIG or plasma-arc welded and resistance welding may be used, either in air or under water. EB welding gives the best results and generally produces a contamination-free narrow weld and heat affected zone, irrespective of material thickness.

Niobium and tantalum possess excellent room-temperature fabrication characteristics, similar to copper, and compatible with all conventional production practices. Large reductions (up to 90%) in recrystallized material can be achieved without intermediate process annealing. Secondary fabrication operations such as stamping, drawing, spinning, or forming into complex shapes can be performed at room temperature. Intermediate anneals are dependent on the amount of work involved. In tube drawing or deep drawing, annealed material should be used initially with reductions of up to 60–80%, and multiple draws possible, before reannealing.

All conventional machining techniques may be used with the proviso that niobium and tantalum have strong tendencies to gall, tear, and adhere (weld) to the cutting tool. This makes tool design and selection of machining lubricant very important. Carbide, coated carbide, and high-speed tools may all be successfully used with water-soluble cutting oils; lathe operations can also use soluble oil emulsions.

Tools should be kept sharp with steep rake angles and fast deep cuts preferred. In practice, most machining procedures that give a satisfactory result with soft copper will generally also give good results with tantalum and niobium.

### 3.15.1.6 Applications

The majority of tantalum is used in electronic applications (capacitors, etc.) with another large percentage utilized in fine chemicals for a variety of purposes. Likewise, the vast majority of niobium is used as alloying additions to steels. However, although only a small minority of either element is used as a primary metal or alloy in its own right, they are generally used in critical applications in corrosion control where few other choices exist (Tables 4 and 5).

### 3.15.1.7 Economics and Availability

There are sufficient worldwide reserves of both tantalum and niobium to last several hundred years at the current consumption rates. The price of these materials is subject to significant market fluctuation depending upon market demand and mine supply. However, tantalum is significantly more costly than niobium with a traditional spread of about 4–5 times. For example, at the end of 2008, the consumer price for recycled niobium was US\$ 55–60 kg<sup>-1</sup>, and for tantalum US\$ 250–260 kg<sup>-1</sup> (by contrast, for molybdenum it was US\$ 35–40 kg<sup>-1</sup> and for platinum \$30 000–40 000 kg<sup>-1</sup>).

**Table 4** Applications for tantalum<sup>6</sup>

<i>Tantalum product</i>	<i>Application</i>	<i>Technical attributes/benefits</i>
Tantalum carbide and nitride	Cutting tools and tool coatings	Increased high temperature deformation, control of grain growth, high hardness
Tantalum oxide	Optical lenses	High index of refraction
Tantalum powder	Capacitors	High dielectric constant, excellent temperature stability, small size
Tantalum and tantalum alloy fabricated products	Sputtering targets	Thin coatings of tantalum, tantalum oxide or nitride coatings to semi-conductors
	Chemical process equipment	Superior corrosion resistance, passivity at high anodic potentials
	Cathodic protection anodes	Attack by body fluids is non-existent.
	Prosthetic devices, hips, plates in the skull	
Tantalum alloy additions	Suture clips, fasteners, fixings	Melting point is 2996 °C, but protective atmosphere or high vacuum required.
	High temperature applications	
	High temperature alloys for air- and land-based turbines (e.g., jet engines)	High temperature reliability and strength, resistance to corrosion by hot gases.

**Table 5** Applications for niobium<sup>6</sup>

<i>Niobium product</i>	<i>Application</i>	<i>Technical attributes/benefits</i>
Ferro-niobium (~60%Nb)	Niobium additive to 'high strength low alloy' steel	Imparts a doubling of strength and toughness because of grain refining
Niobium oxide	Optical lenses, non-reflective coatings	High index of refraction, high dielectric constant
Niobium powder	Capacitors for electronic circuits	High dielectric constant, stability of oxide dielectric
Niobium carbide and nitride	Cutting tools and tool coatings	High temperature deformation, controls grain growth, high hardness
Niobium and niobium alloy fabricated products	Sputtering targets for coatings Cathode protection anodes Chemical processing equipment	Superior corrosion resistance, passivity at high anodic potentials
Niobium–1% zirconium alloy	Sodium vapor lamps Chemical-processing equipment	Corrosion resistance, gettering of oxygen, resistance to embrittlement
Ferro-niobium and nickel–niobium	Additions to turbine blade alloys for air- and land-based gas turbines	Increase in high temperature resistance and corrosion resistance, oxidation resistance, improved creep resistance, reduced erosion at high temperatures
Niobium–titanium; Niobium–tin	Superconducting wires for high-field magnets and resulting applications	Superconductivity at cryogenic temperatures

The relatively high cost of tantalum is a significant limiting factor in its use, especially since much of the corrosion performance can be obtained from niobium. Nevertheless, its mechanical properties, which are typically more than twice that of niobium, can compensate to a large extent for the cost difference and are critical in some applications. Where thin linings are used, the long life and high reliability of tantalum equipment can more than offset its higher initial cost. In many applications, tantalum and niobium (or their alloys) are increasingly specified as either complete replacements for noble metals, or as stable substrates for noble metal coatings, at considerably lower cost for essentially equivalent performance.

### 3.15.2 Electrochemistry

#### 3.15.2.1 Thermodynamics

Tantalum and niobium have remarkably similar electrochemistry that is characterized by their passivity over almost the entire range of pH and potential. Thus, although both metals are more active than zinc, for example, the stability of the passive oxide film against almost all corrosive agents (except fluoride) is remarkable. The only significant difference between the elements, which forms the industrial basis for their separation, is that tantalum displays generally only one oxidation state (+5), while niobium has multiple oxidation states (+2, +4, and +5). This difference is reflected in the *E*–pH (Pourbaix)

diagrams shown in **Figures 1** and **2**, which are otherwise notable for their lack of complexity. Thus, niobium should theoretically passivate at intermediate potentials with, successively, NbO, NbO<sub>2</sub>, and Nb<sub>2</sub>O<sub>5</sub> while tantalum forms just Ta<sub>2</sub>O<sub>5</sub>.

As mentioned above, the metals are relatively susceptible to fluoride which destroys oxide passivity and must therefore be avoided. Also, although not shown on these diagrams, the +5 oxyanions, niobate (NbO<sub>3</sub><sup>–</sup>) and tantalate (TaO<sub>3</sub><sup>–</sup>), are stable in strong alkali, which can lead to dissolution of the passive film and activation of the metals under these conditions.

#### 3.15.2.2 Hydride Formation

Both tantalum and niobium have high solubility and diffusivity for hydrogen. Thus, reducing conditions (i.e., under either a significant partial pressure of hydrogen gas or electrochemical cathodic polarization) will inevitably cause hydrogen embrittlement of Nb/Ta metals and their alloys; predominantly because of hydride formation.<sup>7</sup> Significant amount of hydrogen can be absorbed into solid solution, up to several percent<sup>8</sup> and two hydride phases are known, Ta/NbH (β-hydride, generally substoichiometric) and Ta/NbH<sub>2</sub> (γ-hydride, close to stoichiometric); thermochemical phase diagrams have been constructed to demonstrate their regions of phase stability as a function of temperature and hydrogen pressure.<sup>9</sup> Hydride formation from solid solution is accompanied

**Figure 1**  $E$ -pH diagram for tantalum at a dissolved metal ion concentration of  $10^{-5}$  M.<sup>3</sup>

**Figure 2**  $E$ -pH diagram for niobium at a dissolved metal ion concentration of  $10^{-5}$  M.<sup>3</sup>

by significant local strain that causes cracking of the hydride phases and, hence, generation of a population of defects thus lowering the fracture toughness;<sup>10,11</sup> this comprises the main mechanism for embrittlement.

Despite the rapid diffusion rate of hydrogen in the bcc metals ( $\approx 10^{-9}$  m<sup>2</sup> s<sup>-1</sup> at 298 K,<sup>12</sup>) the observed rate of hydride formation is sluggish. The kinetics of

hydride formation appears to be limited by the presence of the passive oxide film, which acts as a barrier to hydrogen entry. Alloying significantly increases the rate of hydrogen entry (presumably by disrupting the passive film in some way) and this effect can be utilized for hydrogen storage or for hydrogen permeation membranes.<sup>13</sup> Mechanical deformation of the

alloy (presumably with local cracking of the passive film) can also lead to enhanced hydrogen uptake.<sup>14</sup> Both tantalum and niobium act as cathodes when in contact with almost all other metallic conductors and will, in appropriate environments, become severely embrittled because of hydrogen generation, a situation that should definitely be avoided.

### 3.15.3 Corrosion Processes

#### 3.15.3.1 Anodizing

The formation of oxide films on tantalum and niobium can be accomplished by direct electrochemical oxidation, generally, either at constant voltage or at constant current. Thus, tantalum and niobium are part of the family of 'valve metals' (including aluminum, tungsten, titanium, zirconium, and hafnium) that form oxides of increasing thickness under increasing anodic polarization. This process is possible because of the thermodynamic stability of the relevant oxides,  $\text{Ta}_2\text{O}_5$  and  $\text{Nb}_2\text{O}_5$  (in particular, their insolubility in the electrolytes used and their lack of higher oxidation states). Like all other anodic oxides, they tend to be noncrystalline and incorporate species from the electrolyte into the films during their growth. Indeed, the properties of the formed oxide films can vary considerably as a function of electrolyte used in the anodizing process.

There is great interest in (and indeed applications for) the use of tantalum and niobium in electronic capacitors. This is because the dielectric constants of tantalum and niobium oxides are, respectively, about three and six times higher than anodic alumina, which is the traditional material used for electrolytic capacitors (Table 6). This implies that capacitors of equivalent values (in farads) can be made with smaller volumes, a critical factor in miniaturization of electronic circuitry. Traditionally, it is anodized tantalum that has been used for capacitor applications, predominantly because it has the required electrical properties (thermal stability and low loss at high frequencies). Anodized niobium shows considerably poorer electrical properties despite the favorable factors of its dielectric constant, greater availability and lower cost. This is because, during anodizing, as well as forming the preferred  $\text{Nb}_2\text{O}_5$ , suboxides of  $\text{NbO}$  and  $\text{NbO}_2$  may also form, and these are, respectively, conducting and semiconducting.<sup>15</sup> In recent years, however, there has been a greater understanding of the formation of the anodic film on niobium, as well as novel methods of forming dielectric materials, for

**Table 6** Electrical properties of various anodic oxides<sup>17,18</sup>

<i>Metal</i>	<i>Oxide growth ratio (nm V<sup>-1</sup>)</i>	<i>Dielectric constant (at 1 kHz)</i>	<i>Electrolyte</i>
Tantalum	3.65	33	0.26M borate + glycol
Niobium	2.33	60	glycol
Tantalum	3.87	29	0.7M sulphuric acid
Niobium	2.56	65	0.5M boric acid +
Aluminium	1.2	9	0.05M sodium borate

example, by atomic layer epitaxy.<sup>16</sup> Consequently, reliable niobium-based capacitors are now becoming available in the market.

The oxide growth ratio as a function of voltage for anodic film formation is also shown in Table 6. As can be seen, these values can vary considerably from metal to metal and depend on anodizing solution and electrical conditions. The oxide growth ratio derives from a complex interaction of parameters and is principally governed by the densities of metal and oxide, the electric field that is required for the species in the oxide film to migrate, and the efficiency of the film-forming process.

In general, for an anodic oxide film to grow, ions must migrate within the oxide under the influence of the applied voltage (i.e., at a field strength  $\approx 100 \text{ MV m}^{-1}$ ). The current is carried both by anions (e.g.,  $\text{O}^{2-}$ ) that migrate inwards and by cations (e.g.,  $\text{Nb}^{3+}$ ) that migrate outwards.<sup>19</sup> When outwardly migrating cations reach the oxide-solution interface either they may react with the electrolyte, forming more oxide and thus thickening the film, or they may dissolve in the electrolyte, contributing to loss of current efficiency in film formation. Thus, an electrolyte in which the cations have a high solubility is likely to result in lowered film-formation efficiency. At the oxide-solution interface, the electrolyte may generate oxygen gas, further reducing current efficiency. Finally, the field at the oxide-solution interface encourages incorporation of anions from the solution into the film. Thus, anodic films on niobium and tantalum inevitably incorporate a greater or lesser quantity of anion species from the electrolyte concentrated in the film at the oxide-electrolyte interface.<sup>20</sup>

Generally, anodic films on tantalum are of the barrier type, relatively featureless and reminiscent of barrier films on aluminum.<sup>21</sup> The ionic transport

numbers of tantalum and aluminum have been studied in mixed oxides spanning the composition range. Tantalum ions ( $\text{Ta}^{5+}$ ) are shown to migrate more slowly than  $\text{Al}^{3+}$  ions, which is consistent with the respective metal–oxygen bond energies,  $\text{Ta}^{5+}\text{—O}$  being higher than  $\text{Al}^{3+}\text{—O}$ . In addition, the cation transport number for tantalum is lower (0.24)<sup>22</sup> than that for aluminum (0.41).<sup>19</sup> The situation of niobium is complicated by the presence (depending on the formation conditions) of additional  $\text{Nb}^{2+}$  and  $\text{Nb}^{4+}$  species in the oxide,<sup>23</sup> which are detrimental to its performance in capacitor applications. Nevertheless, the general overview is very similar. Thus, electrolyte species (including phosphate but not chloride) incorporate into the film during anodizing.<sup>24</sup> However, recent work has demonstrated a profound difference with niobium in alkaline electrolytes. Thus, in phosphoric acid at pH 2 the transport number for  $\text{Nb}^{5+}$  ions is 0.26 which is similar to that for tantalum.<sup>25</sup> However, when the pH is adjusted with ammonium hydroxide to pH 10, the transport number falls to 0.02 and the dielectric constant rises to more than 80 (from 44 at pH 2). It is thought that this change is due to the relative changes in the incorporation of anionic species into the film, specifically phosphate at low pH and a nitrogen species at high pH.

### 3.15.3.2 Passivity, Corrosion, and Localized Corrosion

As predicted from the Pourbaix diagram, the excellent corrosion resistance of tantalum and niobium is due to the presence of tenacious passive oxide films on the respective metals. Indeed, unalloyed tantalum is indubitably the ‘most passive’ of all metals just below rhodium and above gold in the Pourbaix practical nobility table. Compared with tantalum, niobium is significantly less passive; however, this is merely relative as niobium is still considerably more corrosion resistant than most other materials. Both the metals spontaneously passivate in almost all environments below 100 °C at atmospheric pressure, except those of low water activity and those containing fluoride, the latter being the metals’ (almost only) Achilles heel.

It is extremely difficult to locate literature data on the electrochemistry of dissolution for tantalum or niobium other than in extreme conditions; one must therefore presume that the metals are passive (with consequently low corrosion rates) in most environments. Tantalum is spontaneously passive, with an

extremely low corrosion rate in all mineral acids (except HF), at all concentrations and at all temperatures below 100 °C. It is used to condense and concentrate sulfuric acid and exhibits passivity in this medium at a much higher temperature. The corrosion resistance of niobium is generally inferior to that of tantalum, with alloys of niobium and tantalum being intermediate in performance.<sup>26,27</sup>

Recently, the corrosion of niobium has been re-evaluated in sulfuric (20, 40, and 80%) and hydrochloric (20 and 38%) acids at room temperature, 75 and 95 °C.<sup>28</sup> The metal was found to remain passive under all conditions, but with variations in the passive current density corresponding to changes in the mass-loss (corrosion) rate. Minor pitting was observed only in sulfuric acid at concentrations of 20% and 40%. It was suggested that dissolution of the passive oxide was via a  $\text{Nb}(\text{OH})_4^+$  species, for which species thermodynamic data had recently been obtained.

The pitting (breakdown) potentials of niobium have been investigated in 0.1 M halide solutions.<sup>29</sup> In chloride and iodide up to about 150 V, no pitting or breakdown was observed, and the metal formed an anodic film. In bromide, the breakdown voltage was only 42 V with some slight pitting observed. Likewise, the corrosion behavior of tantalum and niobium was studied in concentrated HBr solution at 25 and 100 °C and, under oxidizing conditions (with added bromine) or reducing conditions (with bubbled hydrogen gas).<sup>30</sup> Tantalum was found to passivate under all conditions studied while niobium corroded slowly at 100 °C with pits of around 5  $\mu\text{m}$  evident. Under reducing conditions, niobium gradually began to corrode actively with hydrogen evolution, while under oxidizing conditions it passivated. Tantalum is thus remarkable in its resistance to pitting corrosion by chloride, bromide and iodide species, and niobium is scarcely far behind.

In contrast to their corrosion resistance in acids, niobium and tantalum corrode at significant rates in strong alkali. Thus, niobium is spontaneously active in NaOH at concentrations greater than 10% and at temperatures above 25 °C.<sup>31</sup> Corrosion leads to the formation of the niobate species,  $\text{NbO}_3^-$ , with the corrosion rate increasing with concentration and time. Tantalum was found to be significantly more resistant than niobium and remained passive in 10% NaOH up to 75 °C and in 15% NaOH up to 50 °C.<sup>32</sup> At higher concentrations and temperatures, the passive film on tantalum dissolved slowly, forming a

polytantalate species. Tantalum–niobium alloys were found to be intermediate in behavior.<sup>33</sup>

### 3.15.3.3 Gaseous Environments

#### 3.15.3.3.1 Oxidation in air

Tantalum and niobium are not resistant to oxidation at high temperatures in air. Reaction with both oxygen and nitrogen occurs; in air, reaction is increasingly rapid for both materials above about 500 °C, leading to catastrophic failure. Thus, these metals and their dilute alloys can only be used in high temperature conditions either in a protective (or nonaggressive) environment, or if coated to prevent reaction with the gaseous environment.

Both metals have significant solubility for oxygen and were found to obey Henry's Law for oxygen solubility between 600 and 1100 °C. At 850 °C, oxygen dissolved at up to 2.3 at.% in pure tantalum and 1.3 at.% in niobium; an alloy of Ta–25% Nb dissolved up to 3.4 at.%.<sup>34</sup> The volumetric expansion on proceeding from metal to oxide (Pilling–Bedworth ratio) is among the largest of the engineering alloys: 2.5 and 2.7 for tantalum oxide and niobium oxide, respectively. This can be compared with 2.1 for chromium oxide, 1.65 for nickel oxide and 1.3 for aluminum oxide. This implies that the oxides form under a considerable compressive stress and, indeed, the oxide scales are generally poorly adherent and greatly influenced by specimen geometry.<sup>35</sup> Oxidation rates at even modest temperatures are high and neither alloy is recommended for use in air above 250–300 °C.

For tantalum, initial oxidation is delayed until the equilibrium solubility for oxygen in the metal has been achieved (which is usually rapid). Afterwards, the oxidation process at temperatures below around 400 °C follows a parabolic rate law, thus indicating diffusion-controlled kinetics across the growing oxide film. For thin oxides, in this regime the oxide is relatively protective. Above 500 °C, oxidation proceeds following a linear rate law; in this regime, the oxide is clearly not protective and indeed oxidation will inevitably become catastrophically rapid as the temperature increases. At temperatures in excess of 1000 °C, the metal will effectively burn in pure oxygen.<sup>36</sup> The scale formed in tantalum consists of pure Ta<sub>2</sub>O<sub>5</sub>; as there is no stable lower oxidation state, there is no other stable oxide. Thicker scales on tantalum tend to comprise parallel layers interspaced with lines of small voids. There is strong evidence

that these voids nucleate over metastable suboxide platelets within a thin, oxygen-saturated layer in the metal immediately under the scale.<sup>37</sup>

Niobium, like tantalum, reacts measurably with oxygen at relatively low temperatures (200 °C) although reaction does not become rapid until above about 400 °C. Niobium is influenced, like tantalum, by the dissolution of oxygen in the metal and by the formation of large compressive stresses in the oxide during scale growth. Again, like tantalum, the oxidation kinetics below about 350 °C are parabolic with thinner oxides relatively protective. Above 400 °C, oxidation is initially linear or parabolic and proceeds at a relatively slow rate; however, after a period of time (decreasing with increasing temperature) breakaway oxidation sets in and the oxidation rate increases markedly up to about 600 °C, then decreases substantially.<sup>38</sup> The scale formed mainly comprises Nb<sub>2</sub>O<sub>5</sub> with the metastable suboxide also present in the metal just beneath the metal–scale interface (as for tantalum). However, unlike tantalum, Nb<sub>2</sub>O<sub>5</sub> increasingly intrudes into the metal from the scale disrupting the formation of the suboxides and causing the rapid breakaway oxidation evident in niobium (and absent in tantalum).<sup>39</sup> The formation of NbO<sub>2</sub> beneath the main scale of Nb<sub>2</sub>O<sub>5</sub> at temperatures above around 600 °C is thought to be the major mechanism behind the decrease in the oxidation rate at this temperature.

Wider application of both alloys would result from improving their oxidation resistance. However, owing to the high cost and density of tantalum, much of the research and industrial effort in improving high temperature oxidation resistance focuses on niobium. There are basically two possible methods for achieving this goal: alloying and application of a protective coating. Extensive early work on binary, ternary, and quaternary alloys of niobium with tantalum, tungsten, titanium, and zirconium was performed and it is indeed possible to reduce considerably the oxidation rate of niobium; for example, in Nb–W–Ti alloys.<sup>40</sup> However, in nonoptimized alloys the oxidation rate is still too rapid to be useful and, furthermore, the alloys are required to have satisfactory high temperature mechanical properties (strength and creep resistance).

More recent alloy developments have involved complex alloys containing titanium, aluminum, chromium, silicon, and hafnium (with other minor elements).<sup>41</sup> Although such alloys have somewhat poorer oxidation resistance at lower temperatures,

at temperatures above 1000 °C the oxidation resistance is comparable to or better than nickel-based superalloys. The requirement of good strength and creep resistance is obtained by alloying to promote the formation of intermetallics; either aluminides (up to 1200 °C) or silicides (up to 1500 °C). Thus, alloys such as Nb–30Ti–9Cr–11Al–11Si show an oxidation rate at 1200 °C of 2–3  $\mu\text{m h}^{-1}$ , compared with unalloyed Nb ( $\gg 125 \mu\text{m h}^{-1}$ ) and nickel superalloys (20  $\mu\text{m h}^{-1}$ ), while having acceptable strength and creep resistance<sup>42</sup>; room temperature fracture toughness, however, remains low.

The alternative method for improving high temperature oxidation resistance is to form adherent, dense and protective coatings on the metal surface. They also need to have excellent oxidation resistance as well as providing an effective diffusion barrier for oxygen (and other species) from the coating into the alloy. Coatings based on the development of single or multiple layers of aluminum, molybdenum and niobium silicide have successfully demonstrated oxidation resistance at temperatures of 1300 °C.<sup>43–45</sup> Such coatings may be applied by pack cementation, chemical or physical vapor deposition and thermal spraying.

### 3.15.3.3.2 Other gaseous environments

The reaction of tantalum and niobium with hydrogen to form hydrides has been discussed above and can occur both electrochemically and from the gas phase. Both materials can react with hydrogen at significant rates even at room temperature, for example, by mechanical action.<sup>46</sup> There has, indeed, been considerable interest in the properties of tantalum and, particularly, niobium for hydrogen storage applications. Thermodynamic data predicts the formation of both the mono- and di-hydride phases, which have been confirmed by observation.<sup>47</sup> Hydriding is used commercially as a method to produce powders of niobium and tantalum and their alloys.<sup>48</sup> Since the metals are generally cathodic to other metals, galvanic coupling must be avoided to restrict the possibility of hydrogen embrittlement.

Although tantalum and niobium also react to form nitrides, in air the dominant reaction will be the formation of the oxide. This is because, first, the kinetics of oxidation are much more rapid and, secondly, the nitrides are themselves thermodynamically unstable with respect to oxidation.<sup>49</sup> However, in a predominantly nitrogen atmospheric, both tantalum and niobium will nitride at temperatures above about 400 °C with parabolic kinetics forming a scale of, respectively, TaN or NbN; in some circumstances

the sub-nitride Ta<sub>2</sub>N or Nb<sub>2</sub>N may also form.<sup>50</sup> Interest in nitriding derives from the extreme hardness of the materials and their potential use as hard finishes for cutting tools, etc, using physical vapor deposition.

Neither tantalum nor niobium are attacked to any great extent by dry or wet chlorine, bromine or iodine liquids or vapors below about 200–250 °C. Tantalum is also virtually uncorroded by HBr and HCl below 370 °C, attack starting at about 375 and 410 °C, respectively. However, as mentioned previously, neither metal has any significant resistance to fluorine or HF.

## 3.15.3.4 Aqueous Environments

### 3.15.3.4.1 Mineral acids

Extensive tests were carried out on the corrosion rates of tantalum and niobium in various highly aggressive media by Bishop in the early 1960s<sup>51</sup> and there is no reason to doubt the data today. Tantalum is essentially resistant to corrosion in nitric acid at all concentrations and temperatures. The corrosion rate in 70% acid at 270 °C is only about 100  $\mu\text{m year}^{-1}$ , which is lower than zirconium and it does not have the latter's sensitivity to halide or metal ion contamination. Niobium is only marginally less resistant to tantalum in nitric acid. Corrosion in other oxidizing acids (e.g., chromic, perchloric) is minimal at all concentrations and temperatures.

Tantalum resists hydrochloric acid at all concentrations up to 190 °C. However, above 25% HCl at 190 °C, the corrosion rate of tantalum (and niobium) rises rapidly (Figure 3) and entry of hydrogen will cause embrittlement. Tantalum is also resistant to hydrochloric acid mixtures even in the presence of sulfuric acid and its salts in all proportions and at concentrations up to boiling point. It is not corroded by phosphoric acid at concentrations up to 85% and temperatures up to 200 °C, provided fluoride ion contamination often found in commercial acid does not exceed 5 ppm. It is essentially completely resistant to perchloric acid, chromic acid, hypochlorous acid, hydrobromic acid, hydriodic acid and most organic acids provided they do not contain fluorides, fluorine or free sulfur trioxide.

Tantalum is resistant to 98% sulfuric acid up to at least 160 °C and even higher temperatures at lower concentrations. Practically, it may be used up to 200 °C in all concentrations and 225–250 °C at concentrations between 80 and 90%. Tantalum is attacked by sulfur trioxide at ambient conditions at

rates higher than  $1 \text{ mm year}^{-1}$  and fuming sulfuric acid, containing sulfur trioxide, attacks tantalum at room temperature as do hydrofluoric and fluorosilicic acids.

Niobium is resistant to mineral acids at lower concentrations and temperatures, especially under oxidizing conditions. **Figures 3** and **4** show the corrosion behavior of niobium and tantalum in laboratory tests in various concentrations of sulfuric, hydrochloric acids and phosphoric acid. It has excellent

**Figure 3** Corrosion rates for tantalum and niobium in HCl ( $25 \mu\text{m year}^{-1}$  was the lower limit of measurement and, where this value is indicated, corrosion rates were generally less than this value; in most cases, considerably so).<sup>53</sup>

**Figure 4** Corrosion rates of tantalum and niobium in  $\text{H}_2\text{SO}_4$  ( $25 \mu\text{m year}^{-1}$  was the lower limit of measurement and, where this value is indicated, corrosion rates were generally less than this value; in most cases, considerably so).<sup>53</sup>

resistance to nitric acid, the rate of attack in 70% acid at  $250^\circ\text{C}$  being only  $250 \mu\text{m year}^{-1}$ . In dilute sulfurous acid at  $100^\circ\text{C}$ , the corrosion rate is below  $15 \mu\text{m year}^{-1}$ , but in concentrated acid at the same temperature it is greater than  $250 \mu\text{m year}^{-1}$ .

In view of the cost of tantalum, and the overall inferior corrosion resistance for critical applications offered by niobium, there is interest in exploring the performance of alloys of tantalum with other elements. The most commercially developed alloys are Ta–Nb materials although Ta–W, Ta–Mo as well as ternary and quaternary alloys of titanium and zirconium where tantalum or niobium ( $\beta$ -phase stabilizers) are significant components. Robin and coworkers have extensively investigated the entire composition range of Ta–Nb alloys in sulfuric, hydrochloric and phosphoric acids,<sup>52,53</sup> and confirmed the earlier results of Bishop while generating isocorrosion curves for the range of alloys in these environments.

In sulfuric acid, the corrosion rates increase with temperature and acid concentration but decrease with time because of slow oxide growth. The addition of tantalum improves the corrosion resistance of niobium with corrosion rates of Ta–Nb alloys intermediate between niobium and tantalum; the corrosion mechanism in the alloys included selective dealloying of niobium. Anodizing of the alloys reduced the short-term corrosion rates but made no difference to the long-term rates. Similar comments apply to exposures in hydrochloric and phosphoric acid except that the alloy with composition Ta–40Nb was confirmed as extremely corrosion resistant with performance similar to tantalum and Ta–W alloys show increased resistance to hydrogen embrittlement.

### 3.15.3.4.2 Alkalis

Neither tantalum nor niobium has satisfactory corrosion resistance in alkaline solution with the passive oxide films dissolving at varying rates depending on the concentration and temperature of the environment (**Table 7**). Corrosion thus occurs by continuous reformation of the passive film; no pitting is seen. Damage to tantalum equipment has been experienced unexpectedly when strong alkaline solutions are used during cleaning and maintenance.

Tantalum is attacked, even at room temperature, by concentrated alkaline solutions. However, tantalum is fairly resistant to dilute alkaline solutions. In one long-term exposure test in a paper mill, tantalum suffered no attack in a solution with a pH of 10. In contrast, niobium is not resistant to alkalis even

**Table 7** Corrosion rates of tantalum and niobium in some alkaline media<sup>54</sup>

<i>Material</i>	<i>Alkali</i>	<i>Temperature (°C)</i>	<i>Corrosion rate (<math>\mu\text{m year}^{-1}</math>)</i>	<i>Embrittlement</i>
Tantalum	NaOH (5%)	98	3–4	No
	NaOH (10%)	20	0.25	No
	NaOH (10%)	98	8–10	No
	NaOH (50%)	38–57	>1000	Yes
	NaOH (50%)	120	>1000	Yes
Niobium	NaOH (73%)	113–129	>1000	Yes
	NaOH (1%)	98	>750	Yes
	NaOH (5%)	98	>1200	Yes
	NaOH (10%)	98	>2000	Yes
Tantalum	KOH (5%)	100	<80	Yes
	KOH (10%)	Boiling	<120	Yes
	KOH (40%)	27	>1000	Yes
	KOH (50%)	100	>1000	Yes
Niobium	KOH (1%)	98	600	Slightly
	KOH (5%)	98	>2500	Yes
	Na <sub>2</sub> CO <sub>3</sub> (10%)	98	>1500	Yes
	K <sub>2</sub> CO <sub>3</sub> (10%)	98	>1500	Yes
	Na <sub>2</sub> PO <sub>4</sub> (25%)	98	>1300	Yes
	Na <sub>2</sub> S (10%)	98	90	No

in dilute solution or in weak alkali (e.g., Na<sub>2</sub>CO<sub>3</sub>) and suffers rapid attack with severe hydrogen embrittlement occurring at higher temperatures of exposure.

#### 3.15.3.4.3 Hydrogen embrittlement and galvanic interactions

As indicated previously, a galvanic couple in which tantalum or niobium is the cathode can prove disastrous because of embrittlement. On the other hand, if either material is the anode they generally passivate so readily in most environments that no damage occurs, and the galvanic current drops to a very low value. Haissinsky<sup>55</sup> studied couples of tantalum with platinum, silver, copper, bismuth, antimony, molybdenum, nickel, lead, tin, zinc, and aluminum in 0.1 N H<sub>2</sub>SO<sub>4</sub>. Except when tantalum was coupled to zinc or aluminum, it was the more negative member (anode) of the couple. However, the galvanic current rapidly decreased as the tantalum passivated. In hydrofluoric acid, tantalum was again more positive than zinc and aluminum, but more negative than platinum, silver, copper, antimony, nickel, and lead. However, in this environment high steady-state currents were observed because tantalum corrodes rather than passivates in fluoride solutions.

Time is an important factor in determining whether tantalum will be damaged by galvanic effects<sup>56</sup> as illustrated in Table 8. However, such data provides only guidance. In practice, it would be dangerous to depend on laboratory tests only to provide information as to whether tantalum is negative in a

given galvanic couple situation. Niobium behaves similarly and if it is cathodic in a galvanic couple the results can prove disastrous because of hydrogen embrittlement. If niobium is the anode in such a couple, it anodizes so readily that no damage occurs and the galvanic current drops to a very low value because of the formation of an anodic oxide film.

Hydrogen embrittlement of these materials may be avoided completely by polarizing the metals anodically (anodic protection). In such cases, the passive film will thicken or at least be maintained. An effective technique is to couple the metal to a material with a very high exchange current density for hydrogen evolution; essentially, a platinum group metal (e.g., platinum, palladium, ruthenium, etc.). This method can also work by surface ion implantation, for example, with platinum,<sup>57</sup> or by the introduction of some platinum species into the environment, where it will deposit onto the exposed surfaces. Another method is to use alloying, typically with rhenium, tungsten or molybdenum.<sup>58</sup> These are believed to function either by doping the passive film and so favorably changing the charge carrier density (so, it is less conductive), or by changing the hydrogen solubility and hydride nucleation mechanism in the alloy.

#### 3.15.3.4.4 Fluorides

Neither tantalum nor niobium has any significant corrosion resistance to fluorine, hydrofluoric acid or indeed environments containing even relatively low concentrations of fluoride. For example, in

**Table 8** Electrochemical potential of tantalum in the indicated solution with respect to various metals<sup>56</sup>

Time after immersion (s)	Coupled metal	Potential of tantalum (mV)		
		3% NaCl	1% HCl	1% NaOH
30	Hastelloy B	−34	−30	−105
3600	Hastelloy B	+3	+1	−5
30	Hastelloy C	−50	−70	−135
3600	Hastelloy C	−3	−3	−5
30	Nickel	−65	−35	−180
3600	Nickel	−3	0	−5
30	Lead	−2	+50	−10
3600	Lead	+60	+55	+30
30	Aluminum	+130	+275	+620
3600	Aluminum	+230	+210	+510
30	304 stainless	−50		
3600	304 stainless	−3		

concentrated nitric acid at 50 °C no significant increase in the corrosion rate for tantalum was observed.<sup>59</sup> However, at 13 ppm fluoride the corrosion rate increased 2–3 times, and above this level increasingly so. Ta–40Nb alloy corroded about 10 times faster than unalloyed tantalum under all conditions studied. Apart from strong alkali, fluoride-containing environments are the only conditions where tantalum and niobium would be expected to corrode at significant rates at ambient temperatures. This is because the passive oxide films are dissolved to form fluoro and oxyfluoro complexes. It is perhaps not surprising that this would occur, since reaction with fluoride forms the basis of the industrial process for purification and separation of the elements.

#### 3.15.3.4.5 Aqueous salts

Tantalum and niobium have excellent resistance to virtually all salt solutions under virtually all conditions of concentration and temperature, including: chlorides, sulfates, nitrates and salts of organic acids, provided (a) they do not contain fluorides, fluorine, and free sulfur trioxide, or (b) hydrolyze to produce strong alkalis.

#### 3.15.3.5 Liquid Metals

Significant interest lies in the use of refractory metals for two main applications: as a constructional material for molten metal die casting and in applications (particularly relating to nuclear) where molten metal coolants might be used. The high cost of niobium and tantalum precludes their use as die materials and, in any case, (unlike molybdenum, which is the preferred die material) they have limited resistance to molten zinc above 450 °C.<sup>60</sup>

Molten metals have many advantages as nuclear reactor coolants. Thus, they have very high heat transfer capability with no change in phase and can operate at atmospheric pressure (unlike water–steam systems, for example). Applications that have been considered (and even implemented in some cases) include: fission reactor coolants, fusion reactor coolants/deuterium breeder blankets and spallation neutron targets (where a high-intensity particle beam from an accelerator impacts upon a heavy metal target, generating a high-intensity neutron source. The liquid metal systems that have been considered include: mercury, gallium, lead, lead–bismuth eutectic, sodium, sodium–potassium eutectic, and lithium.

The degradation of a metallic container material in a liquid metal environment depends upon a number of factors and can manifest in two main ways: dissolution of the container material (or its protective oxide) into the molten environment, embrittlement (liquid metal embrittlement) of the container material with the environment. The mechanisms for liquid metal embrittlement remain complex and unclear, and often depend upon the container–environment combination; however, reaction of the container material with impurities (e.g., dissolved oxygen) in the molten metal and formation of destructive or protective intermetallic compounds between the container material and the environment appear to be among the important factors.<sup>61</sup>

Considerable research was carried out in the 1950s by the then US Atomic Energy Commission<sup>62</sup> on the corrosion resistance of materials in liquid metals, particularly in regard to fast fission reactor coolants and this work is summarized as follows. Liquid bismuth was found to have little action on

tantalum at temperatures below 1000 °C but caused some intergranular attack above this temperature; with no detrimental effects on stress rupture properties up to 815 °C. Niobium was also resistant to bismuth at lower temperatures (up to 560 °C) and it suffered some degree of embrittlement at 815 °C. In molten gallium, tantalum was resistant up to 450 °C, but poor above 600 °C. Niobium was slightly less resistant than tantalum, showing good resistance at 400 °C but poor resistance above 450 °C. Both tantalum and niobium were resistant to liquid lead at least up to 815 °C, possessed good resistance to molten lithium up to 1000 °C and in mercury vapor up to 600 °C. Liquid sodium, potassium or their alloys had little effect on either tantalum or niobium up to 1000 °C if oxygen free. However, in the presence of significant dissolved oxygen, the liquid metals could become corrosive at lower temperatures.

More recent work has shed light on the critical importance of the dissolved impurity levels (particularly oxygen) in the molten metal and also the proposed containment materials. Tantalum exhibited essentially no reaction in liquid lead under oxidizing conditions at 600 °C for 100 h.<sup>63</sup> In liquid sodium or potassium, reaction with the passive oxide layers on niobium and tantalum form ternary oxides whose solubility contribute to the overall corrosion rates. Nitride, carbide and hydride formation is also seen with the corresponding dissolved species.<sup>64</sup> In liquid lithium, however, the oxides on tantalum and niobium are unstable and are reduced to the metal. Additionally, liquid metal embrittlement by lithium, in the form of metal penetration along grain boundaries, occurs when the oxygen levels exceed 400 or 100 ppm in niobium or tantalum respectively.<sup>65</sup>

### 3.15.3.6 Organic Compounds

In general, tantalum is completely resistant to organic compounds and may be used in almost all conditions. However, in environments of low water activity niobium and tantalum show evidence of pitting corrosion (in methanol)<sup>66</sup> and even dissolution (bromine in acetone).<sup>67</sup>

## 3.15.4 Industrial Applications

### 3.15.4.1 Chemical Process Equipment

Tantalum and niobium and their alloys find significant use in process equipment in very corrosive duties that arise in metal pickling, chemicals/petrochemicals manufacture, oil refining and other

operations or in processes that can tolerate only limited metal ion contamination such as pharmaceuticals manufacture. Typical applications include reaction and separation equipment, heaters and heat exchangers, piping and valves, thermowells and rupture discs. The relatively high costs and excellent corrosion resistances of the alloys dictate/permit the use of relatively thin, typically 0.5–1.00 mm sections for heat exchange or as clad/loose linings on cheaper substrates, usually steels, for pressure containment. A common application is in heat exchangers (evaporators and coolers) for the concentration, handling and reconcentration of sulfuric, nitric, hydrohalide and mixed acids. However, the alloys cannot be used in HF or HF-containing fluids, which include commercial, pure phosphoric acid.

### 3.15.4.2 Anodes

Both tantalum and niobium have exceptionally high positive breakdown potentials for pitting corrosion and significant oxygen evolution in chloride environments (>150 V for tantalum and >100 V for niobium in seawater). Thus, they are both ideal substrates either on their own, or as substrates for platinum group metals as nonconsumable anodes and are used in all fluoride-free environments, although niobium is preferred because of its lower cost.

Applications for impressed current anodes include all those where nonconsumable impressed current anode might be specified, for example, in sea and brackish water, brines, concrete and soils. However, platinized niobium anodes are particularly suitable (compared with platinized titanium) for use in high-resistance environments where large positive driving voltages are required to deliver reasonable currents. They are often used, therefore, in deep well ground beds in order to protect long lengths of buried pipe. Although driving potentials up to about 100 V may be used, crevice corrosion can occur at lower driving voltages in the range 20–40 V especially in the presence of impurities such as copper and iron, and under deposits or in mud.<sup>68</sup>

In similar manner, both tantalum and niobium have been explored for use as nonconsumable long-life anodes for electrowinning, electroplating, and oxygen evolution applications.<sup>69,70</sup>

### 3.15.4.3 Medical and *In Vivo* Applications

Tantalum and niobium are very stable passive metals and are completely inert to body fluids and tissues.

In particular, bone and tissue do not recede from tantalum, which makes it attractive as an implant material for the human body. Tantalum's comparatively low strength precludes its use as a structural (i.e., joint) implant although it is, for example, used for bone-support plates. However, its electrical properties are such that tantalum (or anodized tantalum) is used extensively for capacitively coupled electrodes for muscle or nerve stimulation.<sup>71</sup> Its high density provides radioopacity and it has uses as a marker on other larger implant components, where tantalum is usually deposited as a surface layer.

### Glossary

**Oxide dispersion strengthened** A method of strengthening or hardening alloys by dispersing a fine (micron-size) oxide throughout the structure usually by processing the material via powder route. This acts both to pin dislocations (and hence harden the material) and also to pin grain boundaries (and hence limit grain growth and reduce creep at high temperatures).

### 3.16.1 Occurrence and Production

Tungsten is a relatively rare element in nature with soil abundance similar to molybdenum. It is mined predominantly as wolframite (iron manganese tungstate) or scheelite (calcium tungstate) both containing above 70% of tungsten. Due to the high melting point of tungsten, routes to the production of tungsten powder are essential. Thus in processing, and after gravity concentration, most ores are converted to a form in which they can be reduced to the metal. This is generally carried out by initial leaching of the

ore to produce tungstic acid followed by conversion to ammonium paratungstate, calcining to tungsten oxide ( $\text{WO}_3$ ) and then reduction in hydrogen at 800–1000°C to produce commercially pure tungsten powder.<sup>1</sup>

#### 3.16.1.1 General Properties

Tungsten is a transition element in the third row of the periodic table, the elements immediately above tungsten (in Group 6B) being molybdenum and chromium with which tungsten shares many similarities in chemistry (oxidation states from 2 to 6) and metallurgy (body-centered cubic lattice). Tungsten has the highest melting point (3410°C) – more than any metal – while its vaporization point (5550°C) is second only to that of rhenium. Excluding actinides, its density ( $19.3 \text{ Mg m}^{-3}$ ) is the fifth greatest of the elements, being equivalent to gold and only slightly less than the adjacent elements rhenium, osmium, iridium, and platinum.<sup>2</sup>

Commercially pure tungsten has relatively high ultimate tensile strength (1000 MPa at 25°C dropping to 250 MPa at 1500°C) and elastic modulus (410 GPa at 25°C, dropping to 360 GPa at 1500°C).

Thus, a significant fraction of the room temperature mechanical properties are retained at high temperatures.<sup>3</sup> Tungsten also has relatively high thermal and electrical conductivity (about one-third of copper).<sup>2</sup> Tungsten oxidizes relatively easily at elevated temperatures, reacting with both oxygen and nitrogen to form oxides and nitrides; these are generally nonprotective above 300°C. Thus, the processing of and the applications for tungsten must take care to avoid reaction, for example, by use of inert gas or reducing gas blanketing, or necessarily must remove oxides that form after processing.<sup>1</sup> Electrochemically, tungsten is rather similar to molybdenum, dissolving as tungstate ions at pH greater than about 5. However, it does have an extended stability regime for  $\text{WO}_3$  (compared with  $\text{MoO}_3$ ) and therefore tungsten has reasonable stability (is passive) in acidic solutions. Indeed, tungsten, as one of the so-called ‘valve metals,’ may be anodized (e.g., in sulfuric acid) to form a stable, relatively protective film of tungsten oxide.<sup>4</sup>

### 3.16.1.2 Fabrication

There are no refractory materials that can contain molten tungsten; consequently powder metallurgical routes are invariably used in the initial processing of tungsten. Thus, tungsten (and any alloying components) in powder form are generally hydrostatically pressed into billets to a green density of 55–60%. Such billets are then sintered by direct resistance electric arc or electron beam heating to 2500–3000°C in order to increase the density to above 90% and preferably above 93%, in order to permit further mechanical processing.

During processing, care must be taken to avoid pick-up of oxygen, nitrogen, and carbon from the environment. These elements will form, respectively, oxides, nitrides, and carbides generally residing at grain boundaries, which will cause embrittlement of the material and importantly, reduce ductility and limit mechanical working. Typical impurities after powder processing are: carbon – 0.04%, oxygen – 0.023%, and nitrogen – 0.002%. Vacuum arc remelting can significantly lower these values to 0.03%, 0.004%, and 0.001%, respectively.<sup>3</sup>

Tungsten, as a body-centered cubic metal, undergoes a ductile–brittle transition that is a function of temperature, sample dimensions and also impurity levels and alloying content. Generally, this occurs well above room temperature and for commercially pure tungsten (99.95%) the transition temperature is 300–500°C. However, this transition temperature can be

reduced by prior mechanical deformation such that at small section sizes it is possible to successfully undertake wire drawing, extrusion, etc. at room or slightly elevated temperatures. Typically, sintered tungsten billets are initially forged or swaged above the recrystallization temperature at 1600–1700°C in a reducing atmosphere in order to densify them and, by this way, the ductile-to-brittle transition temperature can be reduced to below 100°C. The lowered processing temperature permits easier operation of sheet rolling and wire drawing, although, due to the high intrinsic yield stress of tungsten, working forces are necessarily significantly larger than for other materials. The ductility of tungsten is significant above its ductile-to-brittle transition temperature with a reduction of area of about 20% at 100°C and over 60% at 1000°C.<sup>1</sup>

### 3.16.1.3 Applications

The greatest use (50–55%) of tungsten is as tungsten carbide ( $\text{WC}$  and  $\text{W}_2\text{C}$ ) in the form of metal matrix composite materials such as ‘cemented’ carbide machine tools, hard coatings, etc. Corrosion of cemented carbides, of course, does not involve corrosion of the  $\text{WC}$  particles themselves, but of the cobalt or cobalt–chromium metallic binder. Other uses are in alloying of carbon steel (15–20%) for various purposes, in particular for ‘high-speed’ tool steels, also containing  $\text{WC}$ . Tungsten is also used as an alloying addition to stainless steels (e.g., for enhanced resistance to chloride) and in high temperature nickel-based superalloys. A further quantity is used in the fine chemicals and electronics industry. Only about 15% of tungsten is used in the metallic form.<sup>5</sup>

The main uses of tungsten metal invoke its unique properties of high melting point, high density and intrinsically high strength, and elastic modulus at high temperature. The classical high melting point application is, of course, as incandescent filaments in lighting with other common uses including electric arc electrodes (in welding, arc lamps, etc.), electrical contact materials for relays, etc., and in electron-emitting (thermionic) materials for vacuum valves, etc. An unusual application where the high strength and high melting point of tungsten are both useful is in rocketry components. Regarding high density materials, the main civil applications include yacht keels, moveable ballast in racing cars and aircraft (where the competitive material in both cases is depleted uranium), in sports materials for weight trimming (e.g., professional darts, golf clubs, etc.),

and for radiation shielding where it can be used in significantly thinner sections than the traditional lead materials and is effectively nontoxic in handling.

A new application that is being developed is for military materiel (i.e., high kinetic energy projectiles) where the current use of depleted uranium on the battlefield has, self-evidently, been found to cause serious, and lingering, toxicological and radiation hazards. Although the use of tungsten in this application is not without its own toxicological problems, the immediate and long-term health risks are of a significantly lower order of magnitude compared to uranium. Tungsten also has a generally very low solid solubility with most metallic elements and it has been proposed that this property may be exploited in future (Generation IV) liquid metal fast neutron reactors for power generation.

### 3.16.1.4 Alloys

Tungsten is commonly alloyed to reduce the inevitable decrease in mechanical properties as the temperature is raised, to limit grain growth at high temperatures, and to control thermionic electron emissivity. Alloying is invariably undertaken by powder metallurgical routes and, by this method, it is also easy to incorporate ceramic powders, for example, as oxide dispersion strengthened (ODS) materials.<sup>1</sup>

Tungsten has significant solid solution miscibility only with a few other elements, the most important of which are molybdenum (where a series of alloys up to 50% Mo are in use) and rhenium, which is totally miscible with tungsten and where alloys of up to 25% are useful (Table 1). Interestingly, solid solution alloying with molybdenum reduces the mechanical properties while alloying with rhenium increases the yield stress by up to 15% and significantly increases the alloy recrystallization temperature; it also lowers the ductile-to-brittle transition temperature such that the alloy with 25% Re is fully ductile at room temperature. Unfortunately, the very high cost and limited availability of rhenium limits the significant use of these latter materials.

The high temperature mechanical properties of tungsten and solid solution tungsten alloys may be improved by oxide dispersion hardening. Typically, thorium (especially for electrical applications due to increased electron emissivity) is preferred as it has the best high temperature stability. For incandescent lamp filaments, potassium oxide is frequently used as a dispersant. On processing, this decomposes to produce numerous tiny bubbles in the structure that pin

**Table 1** Chemical composition of selected tungsten alloys<sup>7</sup>

<i>Alloy</i>	<i>Composition (wt)</i>
<i>Commercial purity alloys</i>	
W – powder processed	0.04% C, 0.023% O, 0.002% N
W – vacuum arc remelted	0.03% C, 0.004% O, 0.001% N
<i>Oxide dispersed alloys</i>	
Thorium dispersed tungsten	As above+1–2% ThO <sub>2</sub>
<i>Solid solution alloys</i>	
W–Mo	10–50% Mo
W–Re	3–5% and 25% Re
<i>Binder phase alloys</i>	
W–Ni–Cu and W–Ni–Fe	Usually in grades of 90%, 93%, 95%, and 97% W, balance of Ni+Cu or Ni+Fe

grain boundaries thus restricting grain growth.<sup>6</sup> The final class of alloys essentially comprises tungsten grains embedded within a binder phase (e.g., W with Ni/Cu/Fe/Mo as binder).

## 3.16.2 Corrosion

### 3.16.2.1 Electrochemistry

#### 3.16.2.1.1 Thermodynamics

Tungsten is a base metal with its domain of thermodynamic stability lying completely below that of water (Figure 1). However, it is significantly more noble than molybdenum and particularly chromium, elements that are above tungsten in the same group (VI) of the periodic table. Tungsten tends to dissolve in near neutral to alkaline solutions to tungstate species in association with an alkali metal cation; other cations tend to produce insoluble tungstates. Tungsten has domains of passivity associated with WO<sub>2</sub> and WO<sub>3</sub> with the latter material having low solubility and being stable to further oxidation. This characteristic allows tungsten to be anodized successfully, for example in sulfuric acid, and hence the metal belongs to the family of ‘valve metals.’ Tungsten forms many relatively insoluble complexes, including chloride ions. Its alloying effects are similar to that of molybdenum in that it is added to stainless steels and other alloys to increase the resistance to chloride-induced localized corrosion.<sup>5</sup>

**Figure 1** Pourbaix diagram for tungsten at a metal ion concentration of  $10^{-5}$  M. Reproduced from *HSC: Chemistry*, version 6.12, Outotec Research Oy: Finland, 2007.

### 3.16.2.1.2 Anodic dissolution of tungsten

As implied by the Pourbaix diagram, there are no simple aquo-cations of tungsten; rather tungsten dissolves generally as a tungstate ( $\text{WO}_4^{2-}$ ) above about pH 5, or as tungstic acid ( $\text{H}_2\text{WO}_4$ ) at very low pH. In alkaline solutions above about pH 12, the dissolution kinetics have been found to be Tafel in nature with smooth dissolution to dissolved tungstate anion. The rate limiting step apparently involves a one-electron transfer process (Tafel slope  $\approx 120\text{mV}$  per decade) and has first order kinetics with respect to hydroxide ion concentration.<sup>8</sup> This no doubt masks a complex, step-wise, dissolution mechanism. Controlled dissolution of tungsten is an important process in the semiconductor industry where efficient planarization of tungsten chip layer interconnects is required.<sup>9</sup>

In contrast, below pH 5, tungsten forms a passive anodic oxide film of  $\text{WO}_2$  (at intermediate voltages) or  $\text{WO}_3$  (more commonly). Under galvanostatic anodization, voltages can reach up to 120–150 V at currents between 2 and  $16\text{A m}^{-2}$ . However, the resultant anodic film requires a relatively high (compared with other valve metals) current density to maintain it and this is thought to be due to the significantly higher solubility of the amorphous film compared to crystalline  $\text{WO}_3$ .<sup>10</sup> The dissolution of anodically-formed tungsten oxide in 0.1 M sulfuric acid occurs

under first-order reaction kinetics via hydration to tungstic acid and is significantly more soluble if higher formation currents are used initially.<sup>11</sup>

### 3.16.2.2 Corrosion Processes

#### 3.16.2.2.1 Oxide removal/cleaning

As noted above, it is necessary to carry out many fabrication operations, especially of heavy sectioned material, at temperatures in excess of  $1000^\circ\text{C}$ . Under these conditions, and unless a protective atmosphere is used, the surface of the tungsten will become covered in an oxide scale. The thickness and tenacity of the oxide depends on the temperature used for the fabrication operation. Thick oxide scales may be removed in a molten mixture of 90% sodium hydroxide and 10% sodium nitrite at  $400^\circ\text{C}$  for a few seconds. This attacks tungsten oxide rapidly and care should be taken during this process, in particular the material must be dry, otherwise splashing could occur. On removal the component should be allowed to cool in air before washing the retained salt in hot water. Alternatively, thick oxide layers may be removed by a mechanical abrasion, for example abrasive blasting. Thinner tungsten oxide scales may be removed by immersion in mixed acid etch solutions, for example: nitric acid+HF+water at 1:1:1 ratio.

Lightly oxidized tungsten can be cleaned by heating in 10% caustic soda solution at about 80°C followed by rinsing in water and then dilute hydrochloric acid solution (10%) to neutralize the remaining caustic before finally rinsing in water and drying.<sup>1</sup>

### 3.16.2.2.2 Aqueous corrosion of tungsten and its alloys

Generally, the aqueous corrosion of commercially pure (and oxide dispersed) tungsten depends upon the pH, with passivity expected below pH 5 and active dissolution above pH 5. In practice, the air-formed film on tungsten oxide provides significant protection against dissolution to mildly alkaline conditions (pH  $\approx$  8) while the dissolution kinetics at pH 12 imply a corrosion rate of about 20–30  $\mu\text{m year}^{-1}$ , that is, about one-tenth of iron. Thus, commercially pure tungsten is passive or corrodes relatively slowly in most aqueous conditions except in strong alkali at pH > 12.<sup>12</sup>

Tungsten is generally more active than most common alloying additions except iron, against which it is slightly noble under alkaline conditions. Thus, tungsten might be expected to act sacrificially under immersed aqueous conditions and this has been confirmed in the corrosion of alloys containing copper in the binder phase which suffer from preferential corrosion of the tungsten grains. However, metal bonded tungsten alloys using a Ni–Fe binder phase are generally found to be somewhat more active than tungsten. This may be due to the solubility of tungsten into this phase (in contrast tungsten has negligible miscibility in copper-containing binder phases) and also due to the protective nature of the air-formed passive film on tungsten.<sup>12</sup>

Amorphous alloys of tungsten with niobium, tantalum, zirconium, and chromium, at concentrations from 15 to 50%, have been prepared by DC magnetron sputtering and the corrosion of these materials has been studied in hydrochloric acid at 1–12M. Under these conditions, the deposited films are non-equilibrium, amorphous, and spontaneously passive. Also, generally such alloys have exceptionally low passive current densities.<sup>13</sup>

### 3.16.2.2.3 Electrochemical planarization of electronic interconnects

Electronic integrated circuits frequently comprise deposition of electronic components on multiple layers. Thus, current microprocessors have 7–9 layers and it seems likely that this figure will increase. Copper is used as the electrical connection strips within

each layer while tungsten plugs are used as the inter-layer connections. A critical process after tungsten deposition is ‘planarization,’ which is designed to reflaten the wafer prior to formation of the next semiconductor layer. The process, more properly known as chemomechanical polishing, is essentially a controlled erosion–corrosion process. There are many proprietary solution mixtures that are used but their common feature is that they contain a mild oxidizing agent designed to dissolve the tungsten while leaving the silicon wafer untouched.<sup>9</sup>

### 3.16.2.2.4 Dissolvable implants

There is a significant application for dissolvable body implants in certain applications. For example, stents are often used to secure blood vessels, etc. in the body from, for example, embolisms. While most of such stents are permanent, some are temporary and there is an advantage if they gradually dissolve (i.e., corrode) in the body. Clearly, such materials need to be nontoxic and magnesium alloys are a clear material of choice in such an application. Unfortunately, the corrosion rate of magnesium alloys is generally rather high, they corrode with release of hydrogen gas and they are difficult to locate in X-rays. In view of this, research is currently underway on the use of tungsten stents which are thought to be relatively or completely nontoxic.<sup>14</sup>

### 3.16.2.2.5 High temperature oxidation and corrosion

Tungsten begins to oxidize significantly above about 300°C in dry air forming a  $\text{WO}_3$  scale that grows under parabolic kinetics. Marker studies demonstrate that the growth kinetics are by inwards diffusion of oxygen anions through the anion vacancies in a scale with distinct oxygen sub-stoichiometry (i.e.,  $\text{WO}_{3-x}$ ). The Pilling–Bedworth ratio for  $\text{WO}_3$  is 3.3, which implies that a protective scale is expected but that the growth stresses are relatively large. In view of this, oxide spallation might be expected and, indeed, this occurs rather readily under thermal cycling.<sup>15,16</sup> In contrast to its behavior in dry air, the oxidation of tungsten in steam is characterized by the formation, above about 800°C, of relatively volatile tungstic acid ( $\text{H}_2\text{WO}_4$ ) – or more accurately hydrated tungsten oxide ( $\text{WO}_3 \cdot \text{H}_2\text{O}$ ). Under these conditions, oxidation occurs by linear kinetics and the metal ‘evaporates’ at a rate controlled by the mass transport of water vapor. This process is rapid with rates of up to 1–2  $\text{mg cm}^{-2} \text{h}^{-1}$  at 800°C.<sup>17</sup>

Compared with air, tungsten corrodes more rapidly in carburizing and sulfidizing environments at

high temperature, however, its performance in a chloridizing environment is considerably better than most other high temperature materials and significantly improved molybdenum.<sup>18</sup> In view of this tungsten is added to several alloys to improve the resistance to environments containing chlorine. The chlorination kinetics are similar to those of molybdenum, but considerably slower. Mass changes are linear with time implying that a protective scale does not form. Also, the reaction rate order with respect to the partial pressure of chlorine is about one-half, which implies that the reaction is under chemical rate control with respect to dissociation of chlorine molecules.<sup>19</sup>

### 3.16.2.2.6 Corrosion in liquid metals

Several next generation (Generation IV) nuclear reactor concepts include fast neutron reactor technologies based on liquid metal coolants. These include, for example, the sodium-cooled fast reactor and the lead–bismuth cooled fast reactor. Further, fusion reactor concepts include deuterium fuel breeding using molten lithium or lead–lithium alloys. Finally, specialist applications in nuclear science (e.g., spallation neutron targets, liquid metal ion sources) require the use of molten metals and, hence, containment of such materials is critical.

In view of the limited or zero miscibility of tungsten with many other materials its corrosion performance has been studied in most of these applications. Thus, the corrosion of tungsten in lead and lead–bismuth eutectic was excellent at 600°C with no apparent wetting of the metal and no degradation detected after 100h exposure.<sup>20</sup> Likewise, no degradation of tungsten was evident in liquid lead–lithium eutectic at 800°C. Finally, in liquid sodium minimal signs of corrosion were evident on polished tungsten at 600°C after 1500h of exposure.<sup>21</sup> These results indicate that tungsten clearly has excellent resistance at a wide range of liquid metals and, although it cannot be used as a structural material due to cost and resource limitations, it will find application in critical niche areas.

### 3.17.1 Occurrence and Production

Molybdenum, which with tungsten is below chromium in Group VI of the periodic table, was not discovered as an element until the latter part of the eighteenth century, around the same time as tungsten. Molybdenum and tungsten are relatively rare elements in nature with similar soil abundances and many chemical similarities. Molybdenum assumed industrial significance during the First World War when a shortage of tungsten caused molybdenum to be used as a substitute in alloy steels.

Molybdenum occurs as the primary ore molybdenite ( $\text{MoS}_2$ ) and also in association with other sulfide mineralizations, particularly copper. The original resources for the primary ore are in the United States, China, and in the Russian Federation, while the

majority of molybdenum is now produced as a by-product of copper mining in Chile, Canada, and elsewhere. The current (2006) production of molybdenum amounts to 195 000 tonnes while the estimated global reserves amount to 19 million tonnes giving about 100 years supply at current consumption rates.<sup>1</sup>

Molybdenite is concentrated, from either primary or by-product sources, by froth floatation and then roasted to produce technical grades of molybdenum oxide ( $\text{MoO}_3$ ), from which ferro-molybdenum (for alloying with steel) is produced using an iron thermite reaction. Further purification of  $\text{MoO}_3$  is carried out in a similar manner to tungsten, that is, by chemical purification via an ammonium molybdate intermediate and then reprecipitation of purified  $\text{MoO}_3$ . Pure molybdenum metal and its alloys are

produced via powder metallurgy routes and the metal powder is obtained by direct reduction of purified  $\text{MoO}_3$  using hydrogen.  $\text{MoS}_2$ , which is used as a lubricious additive, is usually obtained directly by purification of molybdenite.<sup>2</sup>

### 3.17.2 General

#### 3.17.2.1 Physical Properties

Molybdenum shares many of its industrially useful properties with tungsten, but it has the advantage of being more readily available and can be much more easily processed due to its lower melting point. **Table 1** compares its physical properties with other selected materials. It has excellent electrical and thermal conductivity, only slightly less than tungsten, but has the advantage of being about half the density. Molybdenum has also one of the lowest linear expansion coefficients of any metal from room temperature to above  $1000^\circ\text{C}$ , which makes its use in glass-to-metal seals and in electronic components important. In addition, its thermal conductivity and linear expansion coefficient are quite close to silicon and also, given its

relatively good electrical conductivity (31% of copper), molybdenum finds use as a chip packaging and interconnect material.

#### 3.17.2.2 Mechanical Properties

Like tungsten, molybdenum retains significant mechanical properties at high temperatures and, hence, is useful in a number of specialist applications although it needs to be protected from significant oxidation above about  $300\text{--}400^\circ\text{C}$ . Like all body centred cubic metals, molybdenum has a ductile-to-brittle transition which is usually at or slightly above room temperature. However, thin sections are generally sufficiently ductile to be formed at ambient temperatures; thicker sections require an increased temperature to avoid cracking. Commercially pure molybdenum has a relatively high yield and the ultimate tensile strength, the values of which are affected by the presence of impurities such as carbon or oxygen. **Table 2** compares some typical mechanical properties for tungsten and molybdenum where it is evident that molybdenum has a further significant advantage in terms of its relatively high specific modulus (stiffness).

**Table 1** Physical properties of molybdenum compared with other elements<sup>3</sup>

	<i>Mo</i>	<i>W</i>	<i>Re</i>	<i>Cu</i>

Crystal structure	bcc	bcc	hcp	fcc

**Table 2** Typical mechanical properties of commercially pure annealed molybdenum compared with other annealed high temperature materials<sup>4–6</sup>

	<i>Molybdenum</i> (at $25^\circ\text{C}/1200^\circ\text{C}$ )	<i>Tungsten</i> (at $25^\circ\text{C}$ )	<i>AISI-321</i> (at $25^\circ\text{C}$ )	<i>Waspalloy</i> (at $25^\circ\text{C}$ )
Density ( $\text{g cm}^{-3}$ )	10.2/10.1	19.3	8.0	8.2
Elastic modulus (GPa)	330/240	420	200	230
Ultimate tensile strength (MPa)	550/140	980	620	1330
Yield stress (MPa)	350/—	750	210	910
Elongation at failure	35%/—	<5%	45%	27%
Specific modulus ( $\text{GPa g}^{-1} \text{cm}^{-3}$ )	31.4/23.7	21.8	25.0	28.0
Specific strength ( $\text{MPa g}^{-1} \text{cm}^{-3}$ )	53.9/13.9	51.8	27.5	162.8

At ambient temperatures the yield strength of molybdenum is similar to normalized low-alloy steel and significantly higher than that of austenitic stainless steel. However, while the low-alloy steels are limited to use at service temperatures of about 550 °C and stainless steels to about 870 °C, unalloyed molybdenum retains useful strength up to 1200 °C (in appropriate protective atmospheres).

### 3.17.2.3 Applications

Molybdenum has a wide variety of industrial applications: as an alloying ingredient in low alloy and stainless steels, in combined forms as an industrial chemical or catalyst, and as a functional metal or alloy. In aqueous environments, molybdenum corrodes at a relatively low rate, generally considerably slower than iron. It is also relatively resistant to acid corrosion and has exceptional resistance to corrosion in hydrochloric acid. Although normally it shows passivity, molybdenum is subject to transpassive oxidation at most pH to a soluble (molybdate) species in aqueous conditions. However, molybdenum is useful in many specialist industry applications especially under mildly oxidizing to reducing conditions. In gaseous atmospheres, molybdenum oxidizes at modestly elevated temperatures in oxidizing environments to form the volatile species  $\text{MoO}_3$ . Thus, the metal is thermodynamically unstable under oxidizing conditions, both aqueous and at high temperature. Without adequate protection, care must therefore be taken to avoid temperatures above about 400 °C in oxidizing gaseous environments.

About one-half of the demand for metallic molybdenum (usually as ferro-molybdenum) is as an alloying addition to carbon steels where it delays the onset of the pearlite transformation and forms strengthening carbide phases in preference to iron.<sup>1</sup> Thus, molybdenum, in concentrations in the range 0.1–1%, is part of the portfolio of alloying additions to steels (e.g., including chromium, molybdenum, vanadium, tungsten, and nickel) that perform this general function. Compared with plain carbon–manganese steels, molybdenum-containing steels have increased strength and creep resistance, at elevated working temperatures.<sup>7</sup> At higher concentrations, that is, above 1% and up to 8%, molybdenum is a critical addition to many grades of steel tool, steel grades that resist softening at high temperatures where it functions by precipitation of alloy carbides ‘high speed steels.’<sup>7</sup> However, the presence of molybdenum (in quantities up to several percent) has relatively minor effects on the corrosion resistance of the ferrous based alloy.

An important secondary use is that about one-quarter of the demand<sup>1</sup> is used as an alloying addition to corrosion resistant alloys such as stainless steels and nickel–chromium alloys. In these applications, molybdenum strongly influences the localized corrosion resistance. Thus, modification of 18Cr–10Ni austenitic stainless steel (i.e., AISI304L) by the addition of at least 2% Mo, results in an alloy (AISI316L) that has substantially improved pitting and crevice corrosion resistance (and lower critical current density for passivation). Further additions of molybdenum (with appropriate metallurgical balancing) give additional improvements.

Molybdenum is also used in much smaller quantities as an alloying addition to titanium (as a beta phase stabilizer) and in high temperature nickel-based superalloys. However, the main applications for unalloyed molybdenum (or molybdenum-based alloys), about 20–25% of the demand, take advantage of its good retention of strength at elevated temperature (up to 1800 °C), its relatively high thermal and electrical conductivity, its low thermal expansion coefficient, its high melting point, its generally good compatibility with molten glasses and ceramics, and its generally low wettability for molten metals. Thus, key applications for molybdenum metal and its alloys include:

- electrical industry (i.e., high current switch contacts, etc.),
- electronic industry (i.e., chip-level interconnects, etc.),
- hot working tools for metal forming,
- dies for molten metal casting especially of zinc (Mo–30W),
- corrosion resistant coatings (for specific chemical processes),
- corrosion resistant equipment for specialist chemical manufacture,
- seals and plugs in glass-lined vessels,
- equipment for glass manufacture: furnaces, crucibles, and stirrers,
- high temperature furnaces and associated components,
- glass-to-metal seals,
- heat shielding in engine parts and in rocketry,
- halide processes for metal purification (e.g., Van Aarke process for Ti and Zr).

### 3.17.2.4 Fabrication

Due to the high melting point of molybdenum, powder processing methods are normally applied whereby

the metal powder is sintered after isostatic pressing typically in the temperature range 1650–1900 °C. Additional arc or electron-beam remelting may then be used to further consolidate ingots; however, care must be taken to avoid excessive grain growth. As implied above, the fabrication of molybdenum and its alloys is largely dictated by its ductile–brittle transition temperature. Although many metal forming operations, for example, on thin sheet and wire less than about 0.5 mm in thickness, can be carried out at room temperature it is cautionary to raise the working temperature of the work piece and die slightly (e.g., 50–200 °C). Thicker sections will require commensurately higher working temperatures; however, above about 550 °C molybdenum starts to oxidize at a considerable rate thus protective atmospheres of hydrogen (e.g., cracked ammonia) are required for significant metal-working of sections above about 650 °C.<sup>2</sup>

All normal fabrication routes can be used to produce molybdenum components, such as metal spinning, flow turning, deep drawing, and pressing. Specific fabrication temperatures are given<sup>8</sup> for various forming processes, including roll forming. Ingots of molybdenum produced either by sintering or by arc-melting are readily forged after heating to about 1500 °C (with appropriate protection against oxidation). Swaging or hot rolling to reduce the ingot size is performed while it is hot, commencing at about 1300 °C and falling as the ductility of the metal

improves to about 700 °C. As the metal thickness decreases, the rolling temperature can also be decreased. Sheet rolling is generally performed at room temperature (or slightly warm) with intermediate anneals at 700–1000 °C. The typical annealing temperature range for full stress-relief of cold worked material lies in the range 870–980 °C. Commercially pure molybdenum may be recrystallised at around 1150–1200 °C; for alloyed molybdenum this temperature generally is increased.

Molybdenum alloys may be machined by any of the standard methods such as milling, turning, drilling, boring, grinding, shaping, threading, and tapping (Table 3). However, the low coefficient of expansion of molybdenum makes it necessary to keep the tool cool when drilling in order to prevent seizure or possible cracking of the metal or tool. Drilling is normally carried out dry but swarf can be carried out with suitable cutting oils. When milling, cutters must be kept sharp and a copious amount of coolant be provided.

It is possible to weld molybdenum using a TIG inert gas-shielded arc-welding process although this is generally more successful on vacuum arc remelted material. When welding, a heat-affected zone is unavoidable and grain growth must be anticipated. These characteristics always give a weld with less ductility than the parent material and no method of welding is entirely satisfactory particularly if the joint is to be stressed. Resistance spot and seam welding is

**Table 3** Some commercially produced molybdenum alloys<sup>2</sup>

<i>Material</i>	<i>Composition</i>	<i>Recrystallization temperature</i>	<i>Applications</i>
<i>Commercial purity: Mo</i>	0.01–0.04% C, <0.02 Fe, <0.01% Ni, Si, <0.003% O, N	1100 °C	Furnace components, windings, etc., glass-metal seals
<i>Clad alloys:</i>			Electrical switch, contact materials, electronic packaging
Mo–Cu	15, 30% Cu	–	
Mo–Ag	35, 50% Ag	–	
<i>Substitutional:</i>			
Mo–W	20–30% W	1200 °C	Molten metal casting
Mo–Re	25–45% Re	1300 °C	Cryogenic ductility
<i>Carbide strengthened:</i>			
TZM	0.5% Ti, 0.08% Zr, 0.03% C	1400 °C	Hot work tooling, dies, glass
TZC	1.2% Ti, 0.3% Zr, 0.1% C	1550 °C	manufacture, spinnerets,
MHC	1.2% Zr, 0.05% C	1550 °C	heating electrodes, etc.
ZHM	0.4% Zr, 1.2% Hf, 0.12% C	1550 °C	
HWM-25	25%W, 1.0% Hf, 0.07% C	1650 °C	
<i>Oxide dispersed:</i>			
PSZ	0.5% ZrO <sub>2</sub>	1250 °C	Furnace components and
MH	0.015% K, 0.03% Si	1800 °C	elements from 1800 to 2000 °C
KW	0.02% K, 0.03% Si, 0.1% Al	1800 °C	
MLR	0.7% La <sub>2</sub> O <sub>3</sub>	1800 °C	
MY	0.55% Y <sub>2</sub> O <sub>3</sub>	1300 °C	

used to join thin sections particularly for electrical and electronic applications. Molybdenum may be brazed using a flame torch and furnace brazing techniques. Small components may also be soldered although they require preplating, usually with nickel.

### 3.17.2.5 Alloys

Molybdenum has sufficient strength to be useful in its commercially pure form. However, as it is not possible to strengthen molybdenum by heat treatment, work hardening is the only viable method of increasing strength in commercially pure material. Like tungsten, molybdenum has poor solubility for most other elements (which is useful for applications involving molten metals); however, solid solution alloys with up to 30% tungsten and 45% rhenium are successfully used. Carbide precipitate and oxide dispersion hardened alloys are also effective with the second phase particles effective in preventing excessive grain growth at very high temperatures.

## 3.17.3 Aqueous Corrosion

### 3.17.3.1 Electrochemistry

#### 3.17.3.1.1 Thermodynamics

Molybdenum is a relatively base metal, similar to iron, with its domain of thermodynamic stability lying

completely below that of water (**Figure 1**). However, it is significantly more noble than chromium and slightly more so than tungsten. Molybdenum has a partial domain of passivity associated with the formation of  $\text{MoO}_2$  across the whole pH range, but is unstable to oxidation from the Mo(IV) to the Mo(VI) state (i.e., it is transpassive) at higher potentials. Thus, molybdenum dissolves at more positive potentials as an oxyanion of molybdic acid depending upon the pH; that is, as  $\text{MoO}_3 \cdot \text{H}_2\text{O}$  (more properly molybdic acid  $\text{H}_2\text{MoO}_4$ ) at low pH, as the hydrogen molybdate anion between pH 3 and 5, and as the molybdate anion above about pH 5–6. Molybdenum tends to form less soluble compounds with species such as sulfur and chlorine. For example, the  $E$ -pH diagram containing 0.1 M sulfur species shows a large domain of stability for  $\text{MoS}_2$  at more negative potentials (**Figure 2**).

Generally, in aqueous conditions, molybdenum and its alloys are effectively passive and show considerably lower corrosion rates than iron (e.g., see **Table 4**).

#### 3.17.3.1.2 Anodic behavior and passivation

The main electrochemical interest in molybdenum arises because of its profound influence on the localized corrosion of stainless steels. Several theories exist for this effect. For example, it has been proposed that the presence of high valency Mo in the chromia passive film reduces the density of cationic charge carriers thus increasing the breakdown potential.<sup>9</sup>

**Figure 1**  $E$ -pH diagram at 25 °C and at a molybdenum ion concentration of  $10^{-5}$  M.<sup>3</sup>

**Figure 2**  $E$ -pH diagram at 25 °C and at Mo ion and S ion concentrations of  $10^{-5}$  and 0.1 M respectively.<sup>3</sup>

**Table 4** Corrosion rates in selected aqueous solutions – 6 day tests<sup>20,21</sup>

Environment (25–35 °C)	Corrosion rate: aerated (mm year <sup>-1</sup> )	Corrosion rate: deaerated (mm year <sup>-1</sup> )
<b>Acids</b>		
HCl: 1–35%	0.03–0.06	–
H <sub>2</sub> SO <sub>4</sub> : 1–30%	0.5–10	–
H <sub>3</sub> PO <sub>4</sub> : 1–30%	0.5–0.3	–
<b>Salts</b>		
NaCl (3%)	0.01	0
NH <sub>4</sub> Cl (20%)	0.005	0
FeCl <sub>3</sub> (20%)	41	34
CuCl <sub>2</sub> (20%)	19	6.5
<b>Alkalis</b>		
NH <sub>3</sub> (0.35%)	0.14	0
NH <sub>3</sub> (29%)	0.02	0
NaOCl (10%)	11	–
NaOH (1%)	0.4	0
NaOH (10%)	0.1	0.025

Other notable theories include: adsorption of molybdate in the outer reaches of the film producing a cation-selective membrane (i.e., reducing chloride ion penetration),<sup>10</sup> local enrichment at actively dissolving sites reducing the local dissolution kinetics,<sup>11</sup> and the reduced solubility of molybdenum chloride and sulphate species affecting pit solution chemistry.<sup>12</sup> However, no general consensus is evident from this data and it is possible that a variety of mechanisms may operate in synergy.

Regarding the anodic behavior of pure molybdenum metal, the Pourbaix diagram implies that molybdenum is passive at intermediate potentials, with the formation of molybdenum dioxide, and that it is subject to transpassive dissolution at more positive potentials. It is generally accepted that molybdenum exhibits passivity over the majority of the pH range; however, the exact nature of this passivity is still in some doubt. The most generally accepted model, consistent with the thermodynamic diagram, is that the passive film consists of MoO<sub>2</sub> which dissolves to a higher valency species at more positive potentials with a higher valence oxide, MoO<sub>3</sub>, present under alkaline conditions.<sup>13</sup> For example, in 0.1 M HCl, X-ray photoelectron spectroscopy (XPS) evidence shows that a film is present on molybdenum that consists of an inner MoO<sub>2</sub> region and an outer layer of MoO(OH)<sub>2</sub>.<sup>8,14</sup> Also, electrochemical impedance spectroscopy (EIS) evidence is consistent with the presence of a passive film at all pH between 1 and 13.<sup>15–17</sup> However, since the anodic polarization curve, for example in sulfuric acid, shows no anodic peak but rather progresses immediately to a potential independent region, some workers have argued that at low pH there is no macroscopic passive film but rather a chemisorbed, strongly-bound oxygen layer.<sup>18</sup> There is general agreement, however, that molybdenum corrodes by transpassive dissolution at all pH at relatively higher potentials, dissolving, most probably via a Mo(V) intermediate state.<sup>19</sup>

### 3.17.3.2 Corrosion Processes

#### 3.17.3.2.1 General corrosion

Arc cast (or arc remelted) molybdenum has greater corrosion resistance than the powder metallurgical product, especially in large sections, which is probably due to the decreased porosity of the cast variety. Components that have been metal sprayed (clad) with molybdenum have considerably worse corrosion resistance than the bulk material, again due to the porosity of the coating. However, where techniques (such as high velocity oxy fuel (HVOF)) can produce dense coatings, the corrosion resistance should improve and cladding of materials such as steel should then become viable. **Table 4** gives corrosion rates in a selection of environments.

In contrast to most other passive metals, molybdenum is relatively unaffected by the presence of halide ions and is consequently relatively resistant to most localized corrosion processes. Molybdenum thus has generally excellent performance in nonoxidizing acid to near-neutral environments (containing halides or otherwise) and particularly in hydrohalide acids (e.g., HCl). However, in neutral-to-alkaline conditions, where molybdenum oxyanions become more stable, dissolution of molybdenum increases. Thus, it is only moderately resistant to aerated solutions of ammonium hydroxide and has fair resistance in 1–10% sodium hydroxide. Molybdenum is significantly less resistant to corrosion in organic acids such as acetic and formic (at 10%, the corrosion rate being 0.2–0.3 mm year<sup>-1</sup>), and in 0.25% benzoic acid (0.25 mm year<sup>-1</sup>) at 100 °C. Combinations of inorganic and organic acids generally lead to increased corrosion rates, for example, addition of 5% sulfuric to 10% acetic acid triples the corrosion rate from 0.33 to about 1 mm year<sup>-1</sup>.<sup>20</sup>

Oxidizing conditions severely reduce molybdenum's corrosion resistance, and aeration causes a significant increase in corrosion. It is therefore rapidly attacked by oxidizing acids such as nitric acid, and by reducing acids containing oxidizers such as HNO<sub>3</sub>, FeCl<sub>3</sub>, CuCl<sub>2</sub>, etc. Also, mercuric chloride causes an intense form of pitting corrosion. It is severely corroded in sodium hypochlorite solutions.

#### 3.17.3.2.2 Galvanic corrosion

In seawater (and presumably most other environments) molybdenum is found to be effectively protected by coupling to aluminum, steel, and magnesium.<sup>19</sup> However, contact with copper is more problematic and may slightly increase or decrease its corrosion

rate in neutral chloride media, but act protectively in acid reducing media. In sodium hydroxide solution, molybdenum acts sacrificially to protect steel and, hence, Mo coatings on steel or cast iron are not always effective in alkaline conditions, especially when significantly porous. Coupling of molybdenum to stainless steels in most environments has no effect on the corrosion rate of either material.

#### 3.17.3.2.3 High temperature water

Refractory and dense materials such as molybdenum, tungsten, and rhenium, are candidates for use in nuclear applications. For nuclear fusion reactor concepts in particular, dense refractory alloys that are resistant to liquid metals and that have good thermal conductivity are essential for efficient heat transfer. Similar requirements are evident in nuclear science applications such as spallation neutron sources. In all such cases, water cooling is likely to be important. To this end, a study of the corrosion of various candidate alloys was undertaken in high temperature pressurized water up to 320 °C.<sup>22</sup>

In flowing, high temperature water containing 400 ppb dissolved oxygen at pH 6–7, molybdenum and its alloys were found to have significantly better corrosion resistance than tungsten and its alloys. Up to 260 °C, neither material is corroded significantly (<50 μm year<sup>-1</sup> for tungsten and ~25 μm year<sup>-1</sup> for molybdenum). However, at 320 °C the corrosion rate of tungsten increased significantly to over 200 μm year<sup>-1</sup> while that of molybdenum was about 4 times lower (~50 μm year<sup>-1</sup>). Alloying with rhenium had a detrimental effect on the high temperature corrosion resistance for both alloys, resulting in grain boundary attack with corrosion rates rising to over 1 mm year<sup>-1</sup> in the case of W–Re alloys.<sup>22</sup>

#### 3.17.3.2.4 Corrosion of molybdenum alloys

The general and galvanic corrosion behavior of both the TZM and Mo–30W alloy are generally at least equal or sometimes superior to that of unalloyed molybdenum in many aqueous solutions of acids, bases and salts apart from strongly oxidizing environments such as in nitric acid.<sup>23</sup>

Sintered and amorphous molybdenum alloys containing significant amounts of tantalum, titanium, chromium and niobium have all been found to offer excellent resistance to strong reducing acids such as hot concentrated hydrochloric, sulfuric, phosphoric, oxalic and formic. For example, a sintered Ti–40Mo alloy corrodes between 1000 and 10 000 times more

slowly than Ti in boiling 35% hydrochloric acid although the corrosion rate in neutral conditions was unaffected.<sup>24</sup> Likewise, binary amorphous Mo–Cr, Mo–Nb, and Mo–Ta alloys all show spontaneous passivity in 12 M HCl with overall corrosion rates, in all cases, significantly less than the individual alloy components.<sup>25</sup>

Ti–15Mo alloys are of interest for prosthetic and replacement body implants (e.g., joints replacements and dental implants) because their relatively low elastic modulus matches better than that of bone. Further advantages include the excellent corrosion resistance of the alloy in body fluids, the relatively low toxicity of molybdenum and, for dental implants, resistance to fluoride.<sup>26,27</sup>

### 3.17.4 High Temperature Corrosion

#### 3.17.4.1 Gaseous Environments

##### 3.17.4.1.1 Oxidation

Molybdenum begins to oxidize significantly in air at about 300 °C. Oxidation becomes rapid at 500 °C and the rate of attack is very rapid by 1200 °C.<sup>28</sup> Below about 400 °C an adherent relatively stable MoO<sub>2</sub> scale is formed and oxidation proceeds according to the parabolic law under diffusion controlled transport through the growing scale. However, MoO<sub>2</sub> is unstable to further oxidation to MoO<sub>3</sub>, which has a significant vapor pressure. Above 500 °C, the vapor pressure of MoO<sub>3</sub> becomes increasingly significant and at some higher temperature, depending on the total partial pressure of oxygen, the rate of evaporation of MoO<sub>3</sub> equals its rate of formation. At this point the volatilization rate becomes extremely rapid following linear kinetics. This sequence is summarized in Table 5.

The formation of molten MoO<sub>3</sub> above 802 °C results in a sudden increase in the oxidation rate because the rate of diffusion of oxygen through a liquid phase is considerably higher than through the solid phases present at lower temperatures. Also, for molybdenum-containing alloys where Mo is less than 50 wt%, the molten oxide can act as a flux for other potentially protective oxide species.<sup>29</sup> Note that the sequence of oxidation is consistent with the thermodynamic properties of the oxides. The activation energy for molybdenum oxidation to MoO<sub>3</sub> in the chemical rate-controlled region was found to be 82 kJ mol<sup>−1</sup> at all temperatures above about 550 °C. At temperatures above around 1100 °C, samples were required to be as small as possible in order to provide enhanced diffusion and, hence, eliminate gas-phase effects. The reaction rate between molybdenum and oxygen in this regime is among the highest measured of all elements and significantly greater than that for tungsten.<sup>27</sup> At exceptionally high temperatures, typically less than 1900 °C and depending on pressure, MoO<sub>3</sub> dissociates to MoO<sub>2</sub>, which then immediately combusts producing a flame.<sup>30</sup>

Secondary ion mass spectrometry (SIMS) has been performed on molybdenum oxide scales of thickness 10–12 μm after oxidation at 500 °C in order to analyze the distribution of MoO<sub>2</sub> and MoO<sub>3</sub>, and the thicknesses of these layers, in the scale.<sup>31</sup> The majority of the scale (>90%) was found to consist of MoO<sub>2</sub> with only a comparatively thin region, less than 0.5 μm in thickness, corresponding to MoO<sub>3</sub> and located at the oxide–gas interface

##### 3.17.4.1.2 Sulphidation

There is considerable interest in the corrosion of molybdenum in sulfidizing environments containing H<sub>2</sub>S or SO<sub>2</sub>/SO<sub>3</sub>. This is in part due to the beneficial

**Table 5** Oxidation sequence for molybdenum as a function of temperature<sup>27</sup>

Oxidation class	Reaction conditions	Oxidation phenomena	Rate-controlling process
1	Below 450 °C	Adherent solid oxide films or scales form	Diffusion control of metal or oxygen through oxide
2	450–800 °C	Solid oxide scales form but MoO <sub>3</sub> volatilizes with lower pressures favoring evaporation	Oxide scales not protective – chemical control via interfacial reaction.
3	802 °C – a transition temperature governed by gas-phase mass transport	Liquid MoO <sub>3</sub> is stable, but volatilizes as soon as oxide forms	Chemical reaction at metal interface with liquid oxide/gas.
4	Above transition temperature	Oxide volatilizes as fast as it forms	Gas-phase transport of oxygen to metal interface.

effect of molybdenum alloying additions for some alloys in reducing hot corrosion in these environments<sup>32</sup> and in part due to the manufacture of MoS<sub>2</sub> catalysts, for example by sulfidation of Mo-containing alloys, which are used in the hydrodesulfurization of petroleum fuels.<sup>33</sup>

Below about 600–700 °C, molybdenum undergoes relatively slow sulfidation, forming MoS<sub>2</sub>. Appreciable reaction rates commence only above about 700 °C where an adherent and generally protective scale of MoS<sub>2</sub> forms by inwards diffusion of sulfur with parabolic reaction kinetics.<sup>34</sup> A change in the sulfidation rate after an initial period has been found to be the result of the formation of an inner layer of Mo<sub>2</sub>S<sub>3</sub>.<sup>35</sup> Sulfidation occurs in any environment containing significant partial pressure of sulfur, such as sulfur vapor, and also in gas mixtures containing sulfur species such as H<sub>2</sub>S or SO<sub>2</sub>.

The extremely low defect density of MoS<sub>2</sub>, coupled with its relatively high melting point, is the main reason why molybdenum is resistant to sulfidation. In contrast, the sulfides of most other functional metals are highly defective and have low melting points (e.g., Fe<sub>1-x</sub>S) and thus offer effectively no protective barrier. In view of this, doping of the sulfide scale is important and controls the sulfidation rate. Thus, in H<sub>2</sub>/H<sub>2</sub>S gas mixtures the sulfidation rate of molybdenum is increased with increasing hydrogen partial pressure and this may be explained by hydride doping of MoS<sub>2</sub>.<sup>36</sup> Likewise, doping of lithium into the scale can increase the sulfidation rate by up to 10<sup>4</sup> times.<sup>37</sup>

#### 3.17.4.1.3 Other environments

Carburization of molybdenum proceeds at high temperatures in vacuum when in contact with graphite components. Reaction only becomes significant above about 1200 °C when a layer of Mo<sub>2</sub>C is formed on the metal surface. This is thought to grow by diffusion of carbon across the layer and is found to thicken with parabolic kinetics. This behavior is similar to that of tungsten but the molybdenum carbide layer grows faster than that for tungsten carbide. The formation of the continuous surface carbide layer in these materials slows their whole-scale carburization and embrittlement under these conditions.<sup>38</sup>

Molybdenum is nitrided in environments containing nitrogen (such as cracked ammonia) at temperatures 800–1200 °C with the formation of a continuous Mo<sub>2</sub>N layer under approximate parabolic growth kinetics. Below 800 °C, the reaction is too slow to measure while above 1200 °C Mo<sub>2</sub>N starts to decompose.

Unlike with carburization, the reaction layer does not appear to provide protection against nitriding of the underlying material, which is likely to become extensively embrittled above around 1000 °C.<sup>39</sup>

In halogenating environments, molybdenum has significantly worse corrosion performance compared with tungsten<sup>40</sup> and the latter is a preferred alloying addition to improve the resistance to environments containing chlorine. The chlorination kinetics are similar to tungsten but considerably faster and no protective scale forms.<sup>41</sup>

### 3.17.4.2 Fused Materials

#### 3.17.4.2.1 Liquid metals

Like tungsten, molybdenum has a relatively low solubility in many molten metals and this has inspired research on the use of molybdenum as a container, or as a process component, in liquid metal environments, particularly in molten metal die casting, and for the nuclear industry (liquid metal cooled fission reactors and fusion reactor concepts). Thus, like tungsten, molybdenum has excellent resistance to molten lead and lead–bismuth alloys.<sup>42</sup> In liquid sodium, molybdenum appears to be unaffected by the dissolved oxygen content but is dependent on dissolved carbon resulting in the formation of a Mo<sub>2</sub>C corrosion product layer. This compares with tungsten, which is dependent on the mass transport of dissolved oxygen in forming ternary layers of oxide.<sup>43</sup> Molybdenum has significant advantages (high temperature strength, etc) in dies for hot metal working and for molten metal dies. In particular, the Mo–30W alloy is extremely resistant to molten zinc and this material is used extensively for zinc dies and as a container/crucible for molten zinc.<sup>44</sup>

#### 3.17.4.2.2 Molten glasses

Molybdenum has good resistance to corrosion/degradation in most molten glasses except those containing lead oxide, which acts as an effective flux. Of course, molybdenum is still susceptible to oxidation above about 400 °C, unless protected by an appropriate gas atmosphere or by a coating. Further information on protective coatings is given below, however, traditionally physical cladding with platinum, or electrodeposition of dense, protective platinum coatings have been used and are effective. The corrosion resistance of molybdenum disilicide in molten glass is also of interest as this material is frequently used as a heating element for temperatures up to 1800 °C in air (due to the formation of protective layers of silica).

Additionally, direct electrical resistance heating of molten glass using molybdenum electrodes is often used (molten glass is an ionic conductor).

The corrosion resistance of molybdenum and molybdenum disilicide in molten soda-glass was studied at 1565 °C over a period of 48 h.<sup>45</sup> Molybdenum was found to have the best corrosion resistance forming a film of MoO<sub>2</sub> that was about 15 µm thick with a total recession loss over the testing period equivalent to about 110 µm. The oxide film on molybdenum was found to be cracked and this clearly allowed additional reaction beneath the film and further corrosion. On MoSi<sub>2</sub>, no protective layer was formed with a loss of recession equivalent to over 315 µm. In all cases the corrosion rate was found to be related to the amount of dissolved oxygen in the glass. In contrast, molten borosilicate (E) glass under similar conditions is a much less aggressive environment, with no significant corrosion of molybdenum noted and considerably less attack on MoSi<sub>2</sub>.<sup>46</sup>

### 3.17.4.3 Protection

The inability of molybdenum to withstand oxidizing conditions at even moderate temperatures has led to many investigations of the means of reducing the oxidation rate. Alloying has not been successful since the loss of key high temperature mechanical properties are unacceptable. Thus, protective coatings appear to be the most effective option. A number of coatings have been developed for molybdenum. At intermediate temperatures, up to about 900–1000 °C, molybdenum can effectively be protected against oxidation by cladding, by thermal sprayed coatings or by electroplating, for example with chromium–nickel.<sup>47</sup>

At higher temperatures, most protective strategies are based on siliconizing, that is, the formation of a coating of molybdenum disilicide. Such coatings generally have similar oxidation resistance to MoSi<sub>2</sub> heating elements up to about 1700 °C. Simple silicide coatings may be formed on molybdenum using a variety of methods, for example using gas-phase diffusion (i.e., cementation) processes. This predominantly forms the favored phase MoSi<sub>2</sub>, however, after the cementation process is completed and during high temperature service, silicon can further diffuse into the molybdenum substrate forming the less protective Mo<sub>5</sub>Si<sub>3</sub> phase. The service life of the coated alloy depends on the initial thickness of the MoSi<sub>2</sub> layer, whether it remains uncracked as also the temperature of operation, as the coating is slowly consumed by

oxidation to silica.<sup>48</sup> More sophisticated coatings, used especially in the glass industry, are based on Si–B–C formulations and these can give more reliable operation to about 1450 °C.<sup>49</sup>

## Glossary

**Widmanstätten** A metallurgical structure showing a characteristic cross-hatched appearance due to the grains is formed along the preferred crystallographic planes.

**Zircaloy** One of a group of alloys used as a nuclear fuel cladding material in light water reactors, thus taking advantage of the relatively low neutron capture cross section and relatively high corrosion resistance of zirconium.

## Abbreviations

**CPI** Chemical process industry  
**DHC** Delayed hydride cracking  
**HAZ** Heat affected zone  
**NHE** Normal hydrogen electrode  
**SCC** Stress corrosion cracking

### 3.14.1 Introduction

Zirconium belongs to Group IVb of the period table being in the second row, beneath titanium and above hafnium. It has similar (but not identical) metallurgical and chemical properties to titanium and may be described as refractory (since their melting points are above the range of iron, cobalt, and nickel), reactive (since they are highly active and have, consequently,

extremely negative equilibrium potentials), and corrosion resistant (since, by virtue of their passivity, they resist attack in many highly corrosive environments). Zirconium and titanium have similar corrosion properties; thus, both metals are excellent for handling seawater, while chromium-containing passive alloys (i.e., stainless steels) are susceptible to localized corrosion in seawater.<sup>1</sup> Moreover, both metals are susceptible to environments of low water activity and are attacked, for example, by halide-containing methanolic solutions; such attack being preventable by the addition of small quantities of water as an inhibitor.<sup>2,3</sup>

Zirconium and titanium are also sister metals of distinctive contrast.<sup>4</sup> The common perception is that zirconium is more suitable than titanium in handling reducing environments (such as hydrochloric and dilute sulfuric acids) than oxidizing environments (such as ferric chloride). Although there is some truth to this perception, it is not always true. Thus, in chloride-free and highly oxidizing environments (e.g., nitric acid), zirconium is often more corrosion resistant than titanium; mistakes can be made when such differences are ignored.

Historically, while the development of titanium resulted from the ever-increasing demands of the aerospace industry, the demand for zirconium arose from the nuclear industry.<sup>5</sup> For this latter application, a suitable structural material to clad nuclear fuel must have good corrosion–oxidation resistance, resistance to irradiation damage, adequate mechanical properties, and

transparency to thermal neutrons. Properly alloyed zirconium meets these requirements. After zirconium became available outside nuclear submarine programs in 1958, research on developing additional applications for zirconium has grown. So, in addition to fuel cladding material for water-cooled nuclear reactors, zirconium began to find uses in the chemical process industry because of its excellent resistance to a broad range of corrosives. Zirconium is also used in specialist surgical tools and instruments and is a highly beneficial alloying addition to iron-, copper-, magnesium-, aluminum-, molybdenum-, and titanium-based alloys. Zirconium is useful as a getter because of its ability to combine with gases at elevated temperatures. Along with niobium, zirconium is superconductive at low temperatures and is used to make superconductive magnets.

### 3.14.1.1 General Characteristics

#### 3.14.1.1.1 Alloy categories

There are two major applications for zirconium and its alloys: nuclear and nonnuclear. Both of these use alloys with low levels of alloying additions and are, thus, based on the alpha microstructure (i.e., the hexagonal close packed lattice) with dilute additions of solid solution strengthening and alpha stabilizing elements like oxygen and tin. However, in niobium-containing alloys, there is the presence of some niobium-rich second phase particles of the body-centered cubic (beta) lattice.

One of the major differences between nuclear and nonnuclear zirconium alloys is in hafnium content. Nuclear grades of zirconium alloys are virtually free of hafnium (not greater than 100 ppm). Hafnium has an enormous effect on absorbing thermal neutrons,

which is critical for nuclear applications and is, therefore, suitable for nuclear reactor control rods that are required to absorb excess neutrons in order to control the uranium fission process. On the other hand, non-nuclear grades of zirconium may contain up to 4.5% hafnium. Hafnium has only a minor effect on zirconium's mechanical and chemical properties.

#### 3.14.1.1.2 Physical and mechanical properties

Zirconium is a lustrous, grayish white, ductile metal whose typical physical and mechanical properties are listed in **Tables 1 and 2**, respectively. For engineering purposes, there are three interesting features of zirconium. First, the density of zirconium is lower than those of iron- and nickel-based stainless alloys. Second, zirconium has a low coefficient of thermal expansion (the coefficient of thermal expansion of zirconium is about two-thirds that of titanium, about one-third that of type 316 stainless steel, and about one-half that of nickel-copper alloys). Third, zirconium has a thermal conductivity ( $22 \text{ W m}^{-1} \text{ K}^{-1}$ ), which is about 30% greater than that of stainless alloys ( $16 \text{ W m}^{-1} \text{ K}^{-1}$ ). These features allow zirconium to be fabricated into compact, efficient equipment, for example as heat exchangers in aggressive environments.

Zircaloy-2, Zircaloy-4, and the niobium-containing alloys are nuclear grades. Zircaloy-2 and Zircaloy-4 contain about 1.5% tin but are different in iron and nickel contents. Thus, Zircaloy-4 has more iron but no nickel in order to minimize hydrogen pick-up. Both alloys are popular in water-moderated reactors, such as boiling water and pressurized water reactors. The Zr-2.5Nb alloy is used in heavy water moderated reactors, such as Canada Deuterium Uranium (CANDU) reactors.

Nonnuclear wrought grades										
Zr700 (R60700)	99.2	4.5	–	–	–	–	–	0.2 (max)	–	0.10
Zr702 (R60702)	99.2	4.5	–	–	–	–	–	0.2 (max)	–	0.16
Zr704 (R60704)	97.5	4.5	1.0–2.0	–	–	–	–	0.2–0.4	–	0.18
Zr705 (R60705)	95.5	4.5	–	2.0–3.0	–	–	–	0.2 (max)	–	0.18
Zr706 (R60706)	95.5	4.5	–	2.0–3.0	–	–	–	0.2 (max)	–	0.16
Nonnuclear casting grades										
Zr702C	98.8	4.5	–	–	–	–	–	0.3 (max)	–	0.25
Zr704C	97.1	4.5	1.0–2.0	–	–	–	–	0.3 (max)	–	0.3
Zr705C	95.1	4.5	–	2.0–3.0	–	–	–	0.3 (max)	–	0.3

Zr700, Zr702, Zr704, Zr705, and Zr706 are non-nuclear grades for wrought materials. Zr702C, Zr704C, and Zr705C are nonnuclear grades for casting materials. Zr700 is an alloy with an oxygen content of less than 1000 ppm which has improved bondability in explosive cladding applications and deep drawing applications. Zr702 is commercially pure zirconium and is most popular for corrosion resistant applications. Zr705 is preferred when strength is an important factor.

Moreover, because recyclable material is generated from fabrication of nuclear fuel cladding, a major impurity in nonnuclear alloys is tin, which is not shown in Table 2. The use of recycled materials lowers the cost of nonnuclear alloys and keeps mechanical properties consistent. The elevated tin

content may affect zirconium's corrosion properties in certain environments. Also, since there is not enough demand in nonnuclear applications to support the production of Zr704, in nonnuclear applications, Zr704 may be effectively Zircaloy-2 or Zircaloy-4.

Zirconium and hafnium form a solid solution at all concentrations. However, the presence of small amounts of hafnium in zirconium does not significantly affect mechanical or chemical properties other than the thermal neutron cross-section. The counterparts of nuclear and nonnuclear grades of zirconium alloys are interchangeable in mechanical properties. However, specification requirements for nuclear materials are more extensive than those for nonnuclear materials. Mechanical requirements only for nonnuclear alloys are given in Tables 3 and 4. It can be seen that Zr705 is the strongest alloy with improved formability.

Additional typical property data are given in Table 5 and in Figures 1 and 2. Table 5 shows that the fatigue limits of zirconium alloys are very notch sensitive. Figure 1 shows that the tensile strengths of zirconium alloys decrease quickly with increasing temperature. Figure 2 indicates that Zr702 and Zr705 creep at low temperatures and stresses. These are important factors to consider in the application of zirconium equipment, particularly at elevated temperatures.

**Table 3** ASTM requirements for the room temperature mechanical properties of zirconium alloys

Alloy	UTS (MPa)	YS (MPa)	Elongation (%)	Bend test radius
Zr700	380 (max.)	305 (max.)	20	5T
Zr702	380	205	16	5T
Zr704	415	240	14	5T
Zr705	550	380	16	3T
Zr706	510	345	20	2.5T

Bend tests are not applicable to material more than 4.75-mm thick. T is the thickness of the bend test specimen.

**Table 4** ASME mechanical requirements for Zr702 and Zr705 used for unfired pressure vessels

Material form and condition	ASME number	Alloy grade	UTS (min) (MPa)	YS (min) (MPa)	Maximum allowable stress in tension for metal temperatures not exceeding °C (MPa)

**Table 5** The  $10^7$  fatigue limits for zirconium alloys

Alloy	Fatigue limit (MPa)	
	Smooth	Notched
Iodide Zr	145	55
Zircaloy or Zr 705 (annealed 2 h at 732 °C)	283	55
Zr-2.5% Nb (Aged 4 h at 566 °C)	290	55

**3.14.1.1.3 Microstructure**

Typical microstructures for the parent metal, heat-affected zone (HAZ), and weld metal of annealed zirconium alloys are shown in **Figures 3–5**. Zr702 is effectively an unalloyed grade (apart from some oxygen) and exhibits an equiaxed alpha structure as shown in **Figure 3(a)**. Most elements have very low solubility in zirconium with oxygen, titanium, hafnium, and scandium the few exceptions. Zirconium

**Figure 1** (Continued)

**Figure 1** Tensile properties vs. temperature curves for zirconium alloys: (a) Zr702, (b) Zr704, and (c) Zr705.

tends to react with many elements to form intermetallic compounds during the production stage, and one of these (and also a major impurity) is iron. Consequently, the most visible second-phase particles in [Figure 3\(a\)](#) are Zr–Fe compounds. There may

also be fine chromium and nickel particles incorporated into these compounds that are well distributed in the alpha structure.

With few grain-boundary pinning precipitates in Zr702, grains in the HAZ grow to much larger sizes generally with an acicular structure ([Figure 3\(b\)](#)) while the weld metal itself exhibits a Widmanstätten structure as shown in [Figure 3\(c\)](#). Welding has a great effect on the morphology of second-phase particles, and this affects the corrosion of zirconium in certain conditions. Like Zr702, Zircalloys or Zr704 exhibit an equiaxed alpha structure in the parent metal ([Figure 4\(a\)](#)), a pronounced acicular alpha structure in the HAZ ([Figure 4\(b\)](#)), and a Widmanstätten structure in the weld metal ([Figure 4\(c\)](#)).

Zr705 exhibits a two-phase structure. It has much finer grain than that of the alpha alloys as shown in [Figure 5](#). It contains both the alpha zirconium phase and the beta niobium phase in the parent metal ([Figure 5\(a\)](#)). The HAZ has a mild change in structure as shown in [Figure 5\(b\)](#). The weld metal has a fine acicular structure of alpha zirconium and beta niobium ([Figure 5\(c\)](#)).

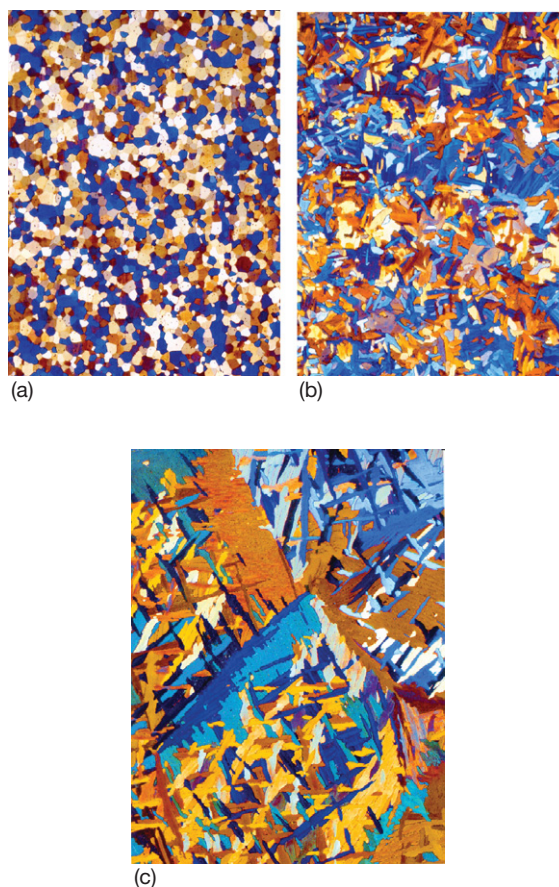

### 3.14.1.2 Chemical and Corrosion Properties

Zirconium is a highly reactive metal, as evidenced by its standard potential of  $-1.53$  V versus the normal hydrogen electrode (NHE) at  $25^\circ\text{C}$ . For comparison,

**Figure 3** Microstructure of Zr702: (a) parent metal of Zr702, (b) HAZ of Zr702, and (c) weld metal of Zr702.

the potentials for titanium, chromium, iron, and nickel are  $-1.53$ ,  $-0.74$ ,  $-0.44$ , and  $-0.25$  V, respectively. Zirconium owes its high corrosion resistance to its strong affinity for oxygen. In an oxygen-containing medium such as air, water, or carbon dioxide, zirconium spontaneously reacts with oxygen at ambient temperature and below to form an adherent, protective oxide film on its surface. This film is self-healing and protects the base metal from chemical and mechanical attack at temperatures up to about  $350^{\circ}\text{C}$ . As a result, zirconium resists attack in most acids, salt solutions, alkaline solutions, and organic media. Zirconium is particularly suitable for handling reducing acids in which most passive alloys have great difficulty in forming passive films. However, in more extreme conditions, such as hydrofluoric acid, hot concentrated sulfuric acid, and certain dry organic halides, a passive

**Figure 4** Microstructure of zircaloy-4 or Zr704: (a) parent metal of zircaloy-4 or Zr704, (b) HAZ of zircaloy-4 or Zr704, and (c) weld metal of zircaloy-4 or Zr704.

oxide cannot readily form and, hence, zirconium is not suitable for handling these media.

In addition, zirconium is susceptible to localized corrosion, such as pitting and SCC in chloride solutions under oxidizing conditions. However, zirconium is not susceptible to crevice corrosion in chloride solutions since the condition in a crevice is often reducing. However, zirconium is susceptible to crevice corrosion in fluoride solutions and sulfuric acid. Examples of review articles on the corrosion of zirconium are given.<sup>6,7</sup>

### 3.14.1.3 Manufacture

#### 3.14.1.3.1 Fabrication

Corrosion failures of zirconium equipment can often be prevented by using alternate choices or methods of design, fabrication (including welding), or by specific heat treatment processes and techniques. Final

**Figure 5** Microstructure of the Zr-2.5Nb alloy or Zr705: (a) parent metal of the Zr-2.5Nb alloy or Zr705, (b) HAZ of the Zr-2.5Nb alloy or Zr705, and (c) weld metal of the Zr-2.5Nb alloy or Zr705.

surface treatment methods can also be applied to modify a surface finish or remove impurities from a surface for improved corrosion resistance. During standard fabrication processes, the surface of the material can become embedded with particles that may affect the corrosion resistance of the zirconium. Since zirconium is relatively a soft metal, abrasive grinding stones may embed aluminum oxide or silicon carbide particles in the material surface causing preferred sites for the initiation of localized corrosion. Abrasive grinding operations performed on zirconium should, therefore, be followed by conditioning with a clean stainless steel brush, clean draw file, or rotary carbide burr to remove any abrasive particles embedded on the surface. If the final part is blasted for a cosmetic appearance, steel shot blast should not be used because the shot will embed into the material surface causing potential localized corrosion failures, especially if used in an acidic chloride environment. However, if the use of steel shot cannot be avoided, then it must be followed by acid pickling or chemical cleaning to remove embedded iron particles.

If other alloys are fabricated near the zirconium vessel, potential sources for embedded particles include grinding and weld spatter of foreign material. For this reason, it is recommended that the zirconium equipment not be welded and fabricated in an area where other materials are being ground, welded, or torch cut. If a zirconium vessel is fabricated in a bay where other materials are being fabricated, then the area should be surrounded by protective barriers and kept clean. Any weld spatter should be removed by stainless steel brushing, grit or glass bead blasting, or light grinding.

It is recommended that hydrostatic expansion be performed when zirconium tubes are expanded into a tubesheet prior to welding. This minimizes the potential for embedded particles on the ID of the tube surface caused during roller expansion as a result of improperly cleaned roller expansion tooling. Corrosion failures in halogen acid environments have been identified where roller expansion of tubes was used. Embedded particles may cause localized pitting attack of the tubes and eventual penetration of the tube wall. For halogen acid applications, all final equipment surfaces exposed to the corrosive environment should be free of iron contamination.

Any tooling used for the fabrication of zirconium should be thoroughly cleaned to remove any contamination left by previous materials. Tooling used for welding or conditioning, such as grinding stones, wire brushes, draw files, etc., should be dedicated for zirconium only. If this tooling has been used previously on other materials, the materials may contaminate the zirconium surface. It is recommended that color coding of the ancillary tooling (files, grinding stones, wire brushes, etc.) be implemented to minimize the potential for cross contamination.

#### 3.14.1.3.2 Problems arising from handling

When zirconium is handled or moved using a forklift and/or lifting straps, protective coverings should be used to prevent the steel from being smeared into the zirconium metal surface. Forklift blades and steel straps will also cause scratches, scrapes, and surface defects that could be detrimental when it is exposed to subsequent forming operations and to certain corrosive environments. To minimize pickup of steel and other metal particles, it is recommended whenever possible to cover the forming dies with a protective covering such as leather, rubber, or some other types of noncontaminating material. This will also minimize the potential for surface damage caused by the steel tooling.

### 3.14.1.3.3 Welding

Generally, zirconium welds exhibit similar corrosion resistance to nonwelded areas except when used at the higher concentrations of sulfuric acid (see corrosion resistance of Zr in [Section 3.14.3.3.1](#)). Improper welding processes, however, can affect the mechanical and corrosion properties of zirconium. Interstitial element pickup, such as hydrogen, nitrogen, oxygen, and carbon in welds will generally not increase the corrosion rate of zirconium. These interstitials may, however, reduce the ductility of the metal and cause premature mechanical failures. Nitrogen contamination caused by plasma cutting with nitrogen gas may increase the corrosion rate of zirconium in nitric acid environments. If any type of cutting operation performed (e.g., oxyacetylene, plasma, laser, etc.) is used, the HAZ should be removed by grinding or machining prior to welding. Water jet cutting should be used for the cutting of zirconium, where possible, to avoid the potential for contamination caused by the heat input. The water jet cut should also be conditioned because this process utilizes an abrasive (i.e., garnet, etc.), which will embed into the zirconium surface.

### 3.14.1.3.4 Heat treatment

Improper heat treatment can result in damage to zirconium in a way which could be deleterious to corrosion resistance. Zirconium can be damaged during heat treatment if the material is placed in a nonoxidizing (i.e., reducing) atmosphere. An atmosphere with excess hydrogen (or with sufficient cathodic polarization) will cause the zirconium to absorb hydrogen and may affect the corrosion resistance of the zirconium. Before heat treatment, the zirconium vessel must be thoroughly cleaned of any surface impurities to prevent contamination during elevated temperature annealing.

When zirconium is cold formed and then heated into the full annealing temperature range, critical grain growth may occur. The grain structure will enlarge in the areas where 2–10% strain energy or cold work has been placed. Cold work of this degree can occur in some cases where plate has been brake press formed into pipe or elbows. On many occasions, formed pipe should be stress relieved at 550 °C for 30 min per 25 mm of thickness. This heat treatment will relieve the stresses caused by forming and welding. If the material is heated to the annealing range of 650–790 °C, the cold worked areas with 2–10% work will recrystallize forming very large grains surrounded by fine grains (i.e., unworked areas). These areas can be either on the outer metal surface, which

is in tension, or on the inner surface, which is in compression and will have large grains with large grain boundaries. These very large areas of accelerated grain growth may be more susceptible to intergranular attack in the higher concentrations of sulfuric acid and should be avoided.

### 3.14.1.3.5 Chemical cleaning

If zirconium equipment is to be used in halogen acids, it is recommended that it has to be cleaned chemically to remove any embedded iron during fabrication. This process should be done by a company experienced in the cleaning of a reactive metal. Smooth and clean surfaces will have the optimum corrosion resistance where rough surfaces are more likely to have surface imperfections, which could initiate premature corrosion attack, especially in the more severe environments. Before any equipment is placed in any corrosive media, it should be cleaned thoroughly to remove oils, grease, paint, and other surface debris.

## 3.14.2 Corrosion

### 3.14.2.1 Oxide Films

Zirconium behaves much like other passive metals, such as titanium, iron, and chromium, relying on passive oxide films for corrosion resistance. However, zirconium is unique in several aspects in the formation and properties of its oxide film. First, the growth of the zirconium oxide film entirely results from the migration of the  $O^{2-}$  ion.<sup>8</sup> That is, a new layer of oxide film continues to form at the metal–oxide interface. The first layer will form spontaneously because of the reactive nature of zirconium and its strong affinity (reactivity and solubility) for oxygen. Additional layers will form at much reduced and decreasing rates resulting from the protective power of the first and additional layers. This also implies that zirconium can conveniently heal any damage done at the metal–oxide interface, provided that the damage is done in an oxygen-containing environment. Very often, there is a thin layer of protective oxide film at the interface even if or when the outer layer is porous and not so protective.

Second, the oxide film on zirconium is most likely  $ZrO_2$ . The existence of oxygen derivatives of zirconium in valence states other than four may be possible but is doubtful.<sup>9</sup> However, the passive films on most passive metals can be oxides in valency of various states. For example, the oxide film on titanium

can be the most protective  $\text{TiO}_2$  film formed in oxidizing media, or a much less protective film as  $\text{TiO}$ ,  $\text{Ti}_2\text{O}_3$ , and their mixture formed in reducing media. Third,  $\text{ZrO}_2$  is a compound that is closer to insulators than to semiconductors. The chemical bonding between zirconium and oxygen is very strong and the transport of current through the film becomes increasingly difficult as the film grows. However, as for many passive alloys, the protective film is unreliable in the presence of flaws on the surface.

Accepting  $\text{ZrO}_2$  as the compound for the passive film on zirconium does not lead to a total agreement among researchers. After all,  $\text{ZrO}_2$  has three different crystalline structures: cubic (c), tetragonal (t), and monoclinic (m). Normally, c, t, and m  $\text{ZrO}_2$  are stable at temperatures between 2680 and 2370 °C, between 2370 and 1240 °C, and below 1240 °C, respectively. Burgers *et al.*<sup>10</sup> reports the film formed on zirconium during anodic polarization in a phosphoric solution to be monoclinic (m)  $\text{ZrO}_2$ , identical to the natural zirconium ore 'baddeleyite'. However, according to Charlesby,<sup>11</sup> the anodic film is cubic (c)  $\text{ZrO}_2$  in the case of polarization in 0.1 N  $\text{HNO}_3$ ; in dilute  $\text{H}_2\text{SO}_4$  or a borate solution, the film is primarily amorphous, but contains some cubic  $\text{ZrO}_2$ . Cox<sup>12</sup> has stated that the passive film formed on  $\text{H}_2\text{SO}_4$  is predominantly the cubic structure with traces of the monoclinic structure.

The oxide film formed on zirconium alloys in water and steam is just as complicated. The oxide scales are known to be predominately monoclinic  $\text{ZrO}_2$ ; however, it has been shown that the oxide layer is under high compressive stress, which may stabilize the oxide in its tetragonal form.<sup>13,14</sup> Studies by Raman spectroscopy and X-ray diffraction have shown that the oxide is a mixture of both (t) and (m)  $\text{ZrO}_2$  structures.<sup>15,16</sup> Godlewski *et al.*,<sup>15</sup> using tapered samples, have shown that in Zircaloy-4 and Zr-1% Nb alloys, ~40% of the oxide film near the oxide-metal interface has (t) structure and the proportion of (t) decreases to ~15% as the distance from the interface increases beyond ~600 nm. Using the reflection high energy electron diffraction technique on the Zr-2.5% Nb alloy, Khatamian and Lalonde<sup>17</sup> detected a mixture of nearly (c), (t), and (m) structures for films of 200-nm thick or less and the (m) structure for the outer layers of films thicker than 800 nm.

It appears that protective oxide films can, therefore, be (m), (t), (c), or their mixtures. It would be incorrect to assume that zirconium and its alloys have, for example, (t)  $\text{ZrO}_2$  to be corrosion and oxidation resistant. After all, to form, for example, (t)  $\text{ZrO}_2$  at a temperature between 1240 and 2370 °C

cannot protect zirconium. All three forms of zirconium oxide are about equally inert. Which one forms on zirconium's surface depends on temperature, alloying elements, environmental composition, and the state of stress in the film. Regardless of its structure, as long as the film is compact and adherent, it is protective.

### 3.14.2.2 Effects of Water

Water is the essential ingredient in aqueous corrosion of most metals and alloys. The presence of water in many environments makes them much more corrosive to common metals. However, with few exceptions, water is zirconium's best friend. For example, a major reason for using zirconium in the nuclear industry (apart from its low neutron capture cross section) is its excellent resistance to water and steam. This capability even extends into highly reducing conditions such as hydrochloric and dilute sulfuric acids. However, zirconium may become vulnerable in certain water-free environments, for example, organic solutions. Without water, zirconium is not able to repair any damage made to the protective film. Hence, the reactive nature of zirconium will be exposed to corrosive attack; the addition of small amounts of water may stop this.

Exceptions include the presence of water in chlorine and fluorine that makes them corrosive to zirconium. Unlike titanium, zirconium resists attack by dry chlorine (titanium may even ignite in dry chlorine). However, zirconium is susceptible to local attack in wet chlorine, which can be regarded as an oxidizing chloride solution (i.e., containing chloride and hypochlorite). Water-containing fluorine is corrosive to both titanium and zirconium.

### 3.14.2.3 Effects of Temperature

Zirconium is regarded as both a reactive and refractory metal because of its high melting point of 1852 °C. However, zirconium is not suitable for high temperature applications because of its reactivity. Zirconium reacts with many metallic and nonmetallic elements at elevated temperatures, that is why zirconium needs a clean surface and argon shielding in welding. Heat treatments may be done in air, but only with a clean surface. For example, to leave a fingerprint on zirconium's surface, this may result in local break-away oxidation as demonstrated in [Figure 6](#).

Zirconium may be used for long-term service generally only when the temperature is 350 °C or lower. For example, the corrosion rate of zirconium changes

little in nitric acid and dilute sulfuric acid as the temperature increases within zirconium's limit. With increasing temperature, the corrosion rate of zirconium may increase but so does the film formation rate. The net change remains small. Of course, in noncompatible media, such as hydrofluoric acid and concentrated sulfuric acid, the corrosion rate of zirconium increases rapidly with increasing temperature.

### 3.14.2.4 Effects of pH

Thermodynamically, zirconium behaves like most passive metals in acidic and alkaline solutions as

**Figure 6** Effect of finger print on zirconium after heating at 760 °C for 30 min.

shown in [Figure 7](#).<sup>9</sup> Zirconium dioxide or hydrated zirconium dioxide dissolves as  $\text{ZrO}^{2+}$  when the pH is less than or equal to 3.5 and as  $\text{Zr}^{4+}$  when the pH is less than about 1. Dissolution as  $\text{ZrO}^{2+}$  is expected to be much slower than as  $\text{Zr}^{4+}$ . Zirconium dioxide retains most of its protective capability until the pH is less than 1 and above 13. In fact, zirconium is one of the few metals that exhibit excellent corrosion resistance over such a wide range of pH and, hence, zirconium equipment can be used in processes that cycle between strong acids and strong alkalis. In this aspect, zirconium is better than other high-performance materials, such as titanium, tantalum, glass, and polytetrafluoroethylene (PTFE), which are generally poor in strong alkalis.

The pH has some effect on the solubility of the oxide film on zirconium, but the effect is not dramatic. Practically, the corrosion resistance of zirconium has little dependence on pH over a wide range.<sup>18</sup> Zirconium dioxide is virtually insoluble in neutral water. It dissolves slightly as the pH increases or decreases as long as pH is not extreme. Slight dissolution conditions for zirconium oxides may have some beneficial effects that are discussed later.

However, pH change may alter the corrosive nature of impurities in a solution. Two important impurities to be considered are ferric ion and fluoride ion. Ferric ion is a common, well-known oxidizing ion that induces pitting on metals and alloys in halide

**Figure 7** The potential–pH diagram of zirconium in water at 25 °C for a dissolved metal ion concentration of  $10^{-5}$  M.

solutions. Fluoride ion has the capability to interfere with oxide formation even at low temperatures. Normally, ferric ion exists in solutions when the pH is less than or equal to 2.5 and when the solution potential exceeds 0.771 V versus NHE.<sup>9</sup> In a nonaerated acid, iron corrodes to yield ferrous ions that are too reducing to induce pitting on most metals and alloys. Ferrous ion tends to become ferric ion in the presence of oxygen. Zirconium resists pitting in iron-containing chloride solutions when the pH is 3 or greater.<sup>19</sup> To control the pitting of zirconium in copper-containing chloride solutions, the pH needs to be 5 or greater.<sup>20</sup>

Furthermore, the corrosivity of fluoride solutions may change dramatically with changing pH. Zirconium is totally defenseless in hydrofluoric acid (HF) at all concentration and temperature as it forms soluble zirconium complex ions in the acid. Although zirconium is not suitable for handling HF solutions, it has some resistance to certain fluoride solutions, such as calcium and sodium fluorides, provided the pH is sufficiently high and the temperature is sufficiently low. The corrosion rate of zirconium in saturated calcium fluoride at pH 5 and 90 °C is close to zero ( $<0.025 \text{ mm year}^{-1}$ ). However, although the corrosion rate of zirconium in saturated sodium fluoride (at pH 7.4) is also effectively zero at 28 °C, it is more than  $1270 \mu\text{m year}^{-1}$  at 90 °C. One major difference between calcium and sodium fluorides is their solubility in water. At room temperature, the solubility of calcium and sodium fluorides are 2 and 4300 ppm, respectively. Hot solutions with a lot of dissolved fluoride ions are potentially corrosive to zirconium. However, the concentration of dissolved fluoride ions is not always proportional to the concentration of the added fluoride salt.

Thermodynamically, hydrofluoric acid exists when the pH is less than or equal to about 3.2.<sup>9</sup> The solution then becomes increasingly corrosive to zirconium, regardless of temperature, with decreasing pH. Therefore, zirconium is not recommended for handling fluoride-containing acids, unless the fluoride ions are effectively removed by complexing.<sup>21</sup> It is important to be aware that there may be overlooked sources of fluoride in particular processes.<sup>22</sup> For example, technical grade phosphoric acid can contain over 1000 ppm of fluoride ion (not necessarily indicated in the specification). Food grade phosphoric acid clearly gives the minimum fluoride content, typically,  $<5 \text{ ppm}$ . Other overlooked sources include contaminated waters, recycled acids, fluxes, and fluorinated compounds.

### 3.14.2.5 Localized Corrosion

#### 3.14.2.5.1 Pitting corrosion

Like most passive metals and alloys, zirconium is susceptible to pitting in all halide solutions except fluoride solutions<sup>23</sup> where it is vulnerable to general corrosion. For zirconium, the susceptibility to pitting is greatest in chloride solutions and decreases as the halide ion becomes heavier. This is the reverse order in the case for titanium, which is highly resistant to pitting in chloride solution but is vulnerable to pitting in iodide solutions.

The pitting potentials of zirconium in 1 N solutions of  $\text{Cl}^-$ ,  $\text{Br}^-$ , and  $\text{I}^-$  are +380, +660, and +910 mV NHE, respectively. These potentials decrease gradually with increasing concentration and decrease rapidly in concentrated halide solutions.<sup>24</sup> Other factors, such as pH,<sup>24</sup> temperature,<sup>24</sup> alloying element,<sup>25</sup> and film quality,<sup>26</sup> also affect pitting potential under certain conditions. The major concern for zirconium is pitting in chloride solutions. Figure 8 illustrates the electrochemical behavior of zirconium and stainless steel. In chloride-free solutions, zirconium is more corrosion resistant than stainless steel and most other passive alloys. However, in chloride-containing solutions, zirconium's advantage disappears in oxidizing conditions. Thus, although zirconium may have a slightly higher pitting potential than stainless steel in chloride solutions, it pits at a much higher rate than stainless steel under a constant potential condition.

Zirconium does not pit in most chloride solutions, such as seawater and underground fluids, because its corrosion potential is often lower than the pitting potential.<sup>27,28</sup> The presence of oxidizing ions, such as ferric and cupric ions, in acidic chloride solutions may increase the corrosion potential to exceed the pitting potential, therefore, pitting may occur. Pitting may also occur when there is an applied anodic potential or when zirconium is coupled with a more noble material, such as graphite or platinum. Nitrate and sulfate ion can inhibit the pitting of zirconium under certain conditions.<sup>20,29,30</sup> Corrosion control measures for pitting and other types of corrosion will be discussed in a later section.

#### 3.14.2.5.2 Crevice corrosion

In chloride solutions, zirconium is among the most resistant of metals to crevice corrosion. Zirconium is not subject to crevice corrosion even in low-pH chloride solutions or chlorine gas. This can be rationalized by the common model proposed for

**Figure 8** The electrochemical behavior of stainless steel and zirconium in (1) chloride-free dilute solutions, (2) chloride-free concentrated solutions, and (3) chloride-containing solutions. Solid line: Common features found in stainless. Dotted line: Common features found in zirconium.

crevice corrosion. In the initial stage of crevice corrosion, metal dissolution and oxygen reduction occur uniformly over the entire surface, including the interior of the crevice. After a short interval, the oxygen within the crevice is depleted because of its confinement, so oxygen reduction ceases within the crevice while metal dissolution continues. This tends to produce an excess of positive charge in the solution, which is necessarily balanced by the migration of negative chloride ions into the crevice. At the same time, positively charged ions, such as  $\text{Fe}^{3+}$ , stay outside the crevice. Similar to the pitting process, metal chloride dissociates into an insoluble hydroxide and a free acid ( $\text{H}^+ + \text{Cl}^-$ ). In addition, the condition within crevices is too reducing to have ferric ions. These changes are actually favorable for zirconium. Consequently, zirconium is not susceptible to crevice corrosion in chloride solutions.

To follow the same model, zirconium would be susceptible to crevice corrosion in fluoride solutions. Crevice corrosion at the contact between zirconium and PTFE would be a special case. PTFE is an inert material and releases few fluoride ions when it is produced by the pressurized process for making virgin materials. It can also be produced from recycled materials by remelting. Recycled PTFE is not as stable as virgin PTFE and may release large amounts

of fluorides. Crevice corrosion of zirconium under PTFE gaskets has occurred several times in acids when recycled PTFE or a less stable type of fluoropolymer had been used.

Furthermore, zirconium is susceptible to crevice corrosion in dilute sulfuric acid when the acid is allowed to concentrate within the crevice.

### 3.14.2.5.3 Intergranular corrosion

Zirconium alloys poorly with most elements and is miscible only with titanium, hafnium, and scandium. Thus, most elements have very low solubility in zirconium and form intermetallic compounds as second phase precipitates. Iron is the major, most visible impurity in zirconium, and zirconium-iron compounds are the most important to consider. Depending on thermomechanical history, zirconium-iron compounds distribute in zirconium in several ways.<sup>31</sup> Mill products typically have the uniform distribution of fine particles. Grain boundaries also are favorite sites for these particles to precipitate. More importantly, these particles tend to be spheroidal under the annealed condition. These particles can become elongated in the HAZ and the weld metal under the as-welded condition as shown in **Figure 9(a)** and **9(b)**. When there are sufficient elongated particles, they tend to form interconnected networks and are,

**Figure 9** (a) The HAZ of as-welded Zr702 and (b) the weld metal of as-welded Zr702.

therefore, not as corrosion resistant as zirconium in most environments. Consequently, the HAZ and the weld metal are susceptible to intergranular corrosion in media such as concentrated sulfuric and hydrochloric acids.

Heat treatment can be used to modify the morphology of the second-phase particles in the HAZ and the weld metal. Heating at 770 °C is effective as shown in [Figure 10](#). After heat treatment, elongated particles become spheroidal similar to those in the parent metal. The resistance of zirconium to intergranular corrosion is, therefore, greatly improved.

#### 3.14.2.5.4 Stress corrosion cracking

Zirconium and its alloys resist stress-corrosion cracking (SCC) in many environments, such as NaCl, MgCl<sub>2</sub>, NaOH, and H<sub>2</sub>S, which are strong

**Figure 10** (a) The HAZ of heat-treated Zr702 and (b) the weld metal of heat-treated Zr702.

SCC-inducing agents on common metals and alloys. Thus, zirconium service failures resulting from SCC are few in chemical applications. The high SCC resistance of zirconium can be attributed to its high repassivation rate. In the presence of water or oxygen, any breakdown in the surface oxide film is quickly healed. The environments known to cause SCC of zirconium include FeCl<sub>3</sub>, CuCl<sub>2</sub>, halogen, or halide-containing methanol and certain other organics, concentrated HNO<sub>3</sub>, liquid mercury or caesium,<sup>32</sup> and 64–69% H<sub>2</sub>SO<sub>4</sub>.<sup>33</sup> Control measures for the SCC of zirconium include:

- avoiding high sustained tensile stresses;
- modifying the environment, for example, changing pH, concentration, or adding an inhibitor;
- maintaining a high-quality surface film, that is, one low in impurities, defects, and mechanical damage;

- applying a small cathodic potential or coupling with a more active material;
- insulating the contact between zirconium and a noble material, such as graphite and platinum;
- shot peening.

### 3.14.2.5.5 Delayed hydride cracking

Hydrogen is well known for its capability to cause damage in many metals and alloys. In titanium and zirconium, which form brittle hydrides, failure can occur by two embrittlement processes. One process is a reduction in the fracture toughness of the metal due to the presence of a high concentration of hydride platelets that have their in-plane dimensions in the crack growth direction. The second process is delayed hydrided cracking (DHC), which is the result of a mechanism of crack initiation and slow propagation.<sup>34</sup>

In DHC, hydrogen diffusion in the metal is required. Gradients of concentration, temperature, and stress are all important factors in controlling diffusivity as given in the general diffusion equation:

$$\mathcal{J} = \frac{DC_x}{RT} \left[ RT \frac{d \ln C_x}{dx} + \frac{Q^* dT}{T dx} - \frac{V^* d\sigma}{3 dx} \right]$$

where  $\mathcal{J}$  is the hydrogen flux;  $D$ , the diffusivity of hydrogen at any point  $x$ ;  $C_x$ , the concentration of hydrogen at any point  $x$ ;  $R$ , the gas constant;  $T$ , the temperature;  $Q^*$ , the heat of transport of hydrogen in metal;  $V^*$ , the volume of transport of hydrogen in metal; and  $\sigma$  is the tensile stress (a compressive stress would have a negative value).

That is, hydrogen is driven by three forces to an area of lower concentration, colder temperature, and higher tensile stresses. Since DHC may occur at low temperatures in a matrix of uniformly distributed hydrogen, its mechanism is believed to be as follows: stress gradients at stress concentration sites attract hydrogen, resulting in local hydride precipitation, growth, and reorientation. When the growing hydride reaches some critical size, the hydride either cleaves or the hydride–matrix interface opens up to nucleate a crack. Once a crack has nucleated, propagation occurs by repeating the same process at the crack tip and, as such, is a discontinuous process. It should be noted that the formation of hydrides is not a necessary requirement for this mechanism to operate, as is the case in delayed hydrogen embrittlement in high-strength steels.

Stress and stress gradient are two necessary requirements for DHC to occur and, fortunately, they are controllable. High stresses without gradients

will not induce DHC. Hydrogen cannot move when high stresses are uniformly distributed in the structure. High-stress gradients are needed to move hydrogen but cannot be created without high stresses. High stresses are also required in fracturing hydride.

Stress relieving is one of the most effective measures in preventing DHC. It takes considerable time for hydrogen to reach the highly stressed area and to precipitate out as hydride platelets. Furthermore, the platelets must grow large enough for cracking to occur. Depending on many factors, it sometimes takes 2 years for DHC to happen, but 5 weeks after welding is the shortest known period for Zr705 to suffer DHC at room temperature. This provides a base for the Boiler and Pressure Vessel Code of the ASME (Section VIII, Division 1, Subsection C, UNF-56, (d), 1992, p.183) to add the following guideline:

Within 14 days after welding, all products of zirconium Grade R60705 shall be heat-treated at (538–593 °C) for a minimum of 1 h for thicknesses up to 1 in. (25.4 mm) plus ½ h for each additional inch of thickness. Above 800 °F (427 °C), cooling shall be done in a closed furnace or cooling chamber at a rate not greater than 500 °F h<sup>-1</sup> (260 °C h<sup>-1</sup>) divided by the maximum metal thickness of the shell or head plate in inches but in no case more than 500 °F h<sup>-1</sup>. From 800 °F, the vessel may be cooled in still air.

### 3.14.2.6 Galvanic Corrosion

With the naturally occurring oxide film, zirconium often assumes a noble potential in most environments. As an example, the galvanic series in seawater is close to the nobility of noble materials. Since zirconium is more corrosion resistant than most materials in a wide range of corrosives, zirconium is likely the cathode in most cases. The material in contact with zirconium could corrode at a much faster rate. The risk for zirconium is absorption (as cathode) and, hence, hydrogen embrittlement.

However, in incompatible environments, such as hydrofluoric acid and concentrated sulfuric acid, zirconium may assume an active potential. Moreover, zirconium may be activated at vulnerable sites when it is in contact with a noble material in chloride solutions. Graphite and carbides in the powder form can be very effective in promoting galvanic corrosion on zirconium since a small amount of powder may produce a very large cathodic area. The effect of coupling with graphite on the corrosion of zirconium in boiling 20% HCl is shown in Table 6.<sup>20</sup> It is

**Table 6** Effect of graphite-coupling on the corrosion of zirconium in boiling 20% HCl after 4 weeks of exposure

Specimen area (cm <sup>2</sup> )		Area ratio graphite/ zirconium	Corrosion rate, mm year <sup>-1</sup> (mpy)
Graphite	Zirconium		
–	31.0	0	0.013 (0.51)
5.9	31.0	0.19	0.013 (0.51)
24.8	5.0	4.96	0.0173 (0.68) <sup>a</sup>
27.0	2.5	10.8	0.239 (9.4) <sup>a</sup>

<sup>a</sup>Localized corrosion.

evident that the effect can be dramatic when the surface area of graphite is significantly larger than that of zirconium.

The effect of galvanic coupling to carbon-based materials is common in chemical equipment due to their popularity and the availability of various forms. Carbon-based materials are used as structural materials, gaskets, additives to lubricants, etc. Galvanic effects induced by carbon-based materials should be appraised not just for zirconium but also for other common metals and alloys.

### 3.14.2.7 Microbiologically Influenced Corrosion

Microbiologically induced or influenced corrosion (MIC) occurs as a result of the presence and metabolism of living organisms in the corrosion environment or on the corroded material. Regardless of the mechanism, MIC can cause large damage to process equipment when natural waters are used in hydrostatic tests or as cooling fluids. However, results of long-term tests in natural waters indicate that zirconium is immune to MIC.

The organisms of greatest concern are sulfate-reducing bacteria. Metabolic processes may produce corrosives, such as sulfuric acid, inorganic or organic sulfides, and organic acids. Common metals and alloys have a high affinity for sulfur and its compounds. As a result, metabolic products simply make it too corrosive for common metals and alloys. Conversely, zirconium has little affinity for sulfur and its compounds. Zirconium resists attack by most inorganic and organic acids as well. Metabolic products are not corrosive to zirconium. In addition, changes in oxygen potential, salt concentration, pH, etc. from organisms do not degrade zirconium's corrosion resistance. Cathodic depolarization associated with anaerobic growth is unfavorable to certain metals and alloys but not to zirconium.

### 3.14.2.8 Erosion–Corrosion

Erosion is defined as accelerated corrosion resulting from the conjoint action of corrosion and erosion in the presence of a moving corrosive fluid. This type of attack is highly dependent on fluid flow-rate and corrosivity. It is particularly prevalent in areas where high local turbulence, impingement, or cavitation of the fluid may occur on metal surfaces. Solids that are suspended in fluid may result in abrasion, which may also drastically accelerate metal removal.

In compatible environments, zirconium forms a hard, tenacious ZrO<sub>2</sub> surface film that provides an excellent barrier to erosion–corrosion. Also, zirconium can quickly repair damage done to the film in environments containing oxygen. Consequently, zirconium can withstand many corrosives at high flow rates. To study this, a corrosion test loop was constructed to investigate the effects of flow rate and heat flux on the corrosion of zirconium tube specimens.<sup>35</sup> No effect was detected when the test conditions were 50% sulfuric acid at 166 °C flowing at 2.1 m s<sup>-1</sup>.

Many passive alloys have the difficulty of forming protective films on their surfaces in sulfuric acid, and they are, therefore, vulnerable to erosion–corrosion in the acid. This is demonstrated in Figure 11.<sup>36</sup> In a sulfuric acid-based mixture, the corrosion of zirconium is insensitive to increasing rotation speed up to 10 000 rpm. On the other hand, corrosion of Alloy C-276 increases continuously from low speed to high speed under the same test conditions.

### 3.14.2.9 Fretting Corrosion

Fretting corrosion results from the combined effects of wear and corrosion and takes place when vibration contact is made at the interface of tight-fitting, highly loaded surfaces, such as between the leaves of a spring or in rolling contact bearings. Factors affecting fretting corrosion include contact load, amplitude, frequency, temperature, and corrosivity of the environment.

Fretting corrosion is a concern for zirconium, since zirconium is a soft and reactive metal. It occurs when zirconium's protective oxide film is mechanically damaged or removed. Measures should be taken to control fretting corrosion. Fretting corrosion on zirconium may be avoided by proper design and fabrication, or through the addition of a heavy oxide coating to combat mechanical effects. This coating drastically reduces friction and prevents the removal of the protective oxide layer.

### 3.14.2.10 Surface Condition

Corrosion is a surface phenomenon, so surface condition is an important factor in the corrosion of metals and alloys. It plays an important role not just in the initiation but also in the propagation of localized corrosion. The corrosion resistance of zirconium is not affected by common surface features such as scratch and heat tint, but may be degraded by embedded particles such as iron and silicon carbide in oxidizing chloride solutions. As indicated in [Figure 12](#), zirconium with different surface conditions has a wide range of rest potential in a hydrochloric acid solution.<sup>20</sup> The potential of pickled zirconium is low and stays low. The potential

of zirconium with SiC abraded surface increases quickly to reach the breakdown potential. In chloride solutions, it is preferred for zirconium to have a low potential that is below the breakdown potential. Pitting is therefore avoided. Zirconium with a clean, smooth surface is expected to have the optimum resistance to localized corrosion including pitting, SCC, and DHC.

### 3.14.2.11 Tin in zirconium

Zircaloy recycling is a major source for zirconium in making zirconium alloys and it can be noted that there may be more than 2000 ppm tin in Zr702 without violating the chemical requirements given in [Table 2](#).

**Figure 11** Results of rotating cylinder electrode tests in a mixture of sulfuric acid, organic acids, and water at 100°C.

**Figure 12** Surface effect on the rest potential of Zr702 in 10% HCl + 500 ppm ferric ion at 30°C.

Advantages of utilizing Zircaloy recycle include consistent mechanical properties, improved corrosion-oxidation resistance in water and steam, and reduction in cost and material conservation. Small amounts of tin may be beneficial or acceptable for Zr702. However, there are cases to implicate that zirconium with a sufficiently high tin content has degraded corrosion resistance in certain environments. Zircaloys have a mechanical strength advantage over Zr702 and, hence, have been used in the manufacture of fittings for corrosive applications. Zircaloy fittings have failed in hot glacial acetic acid after 3 weeks to 5 months of service.<sup>37</sup> Zr702 and Zr705 are known to be highly compatible with acetic acid. Thus, the failures of Zircaloy can be attributed to the high tin content ( $\sim 1.4\%$ ) in the alloys.

The zircaloy family of materials was developed for improved corrosion properties in high pressure water and steam primarily as a cladding material for nuclear fuel. Tin additions to zirconium were originally intended to offset the harmful effects of impurities like nitrogen where they were often higher than 40 ppm. However, the nitrogen content of the present zircaloy materials is much lower, and higher levels of tin can be more harmful than beneficial in this circumstance. Thus, the corrosion resistance of zircaloy-4 in 400 °C steam improves with decreasing tin content from 1.41 to 0.09%.<sup>38</sup> It should be noted that the test temperature was much higher than the operating temperature of zirconium equipment in nuclear reactor (pressurized water) environments (285–350 °C). This effect of tin is expected to decrease with decreasing temperature.

Results of 28-day tests show that the presence of greater than 3000 ppm tin is much more critical to zirconium in boiling sulfuric acid than in boiling acetic, hydrochloric, and nitric acids. The critical tin content in zirconium for sulfuric acid service seems to be between 2000 and 3000 ppm.<sup>39</sup> However, the distribution of tin in zirconium is not uniform. To take the fluctuation into consideration, the target point for the tin content in Zr702 should be set at 1500 ppm, if 2000 ppm proves to be the limit for the alloy in sulfuric acid service.<sup>39</sup> Recently generated data seem to support this recommendation.<sup>40</sup>

### 3.14.3 Corrosive Environments

#### 3.14.3.1 Pressurized Water and Steam

Due to its passivity, zirconium is suitable for nuclear applications since water-cooled reactors operate with oxygen or hydrogen charged coolant at temperatures

from 286 to 350 °C. The corrosion and oxidation of unalloyed zirconium in high temperature water and steam are irregular; that is, oxide growth is not generally self-limiting. This behavior is related to variations in the impurity content of the metal with nitrogen and carbon impurities particularly harmful. The oxidation rate of unalloyed zirconium increases markedly when nitrogen and carbon concentrations exceed 40 and 300 ppm, respectively.<sup>41,42</sup> The irregular behavior of unalloyed zirconium has stimulated alloy development programs. Zircaloy-2, zircaloy-4, Zr-2.5Nb, and Zr-1Nb ('Zirlo') are the most important alloys developed for nuclear applications because they are more reliable and predictable for use in hot water and steam, in addition to being stronger.

During oxidation at elevated temperatures, zirconium alloys initially form a tightly adherent oxide film at a rate that is at first quasicubic but, after an initial period, undergoes a transition to linear behavior. Unlike the white, porous oxide films on unalloyed zirconium, the oxide film on zircaloy-2 remains dark and adherent throughout transition and in the post-transition region. Zircaloy-4 differs in composition from zircaloy-2 by having a slightly higher iron content but no nickel. Both variations are intended for reducing hydrogen pickup during corrosion but with minimal effect on overall corrosion resistance during reactor operation. Hydrogen pickup detrimentally influences fuel cladding performance with regard to hydride formation. For example, in water at 360 °C, the hydrogen pickup for zircaloy-4 is about 25% of the theoretical quantity, or less than half of that for zircaloy-2. In addition, hydrogen pickup for zircaloy-4 is less sensitive to hydrogen overpressure than that for zircaloy-2. For both alloys, hydrogen pickup is greatly reduced when dissolved oxygen is present in the medium.<sup>41</sup>

The Zr-2.5Nb alloy is considered somewhat less resistant to corrosion than the zircaloys with exceptions. Nevertheless, the Zr-2.5Nb alloy is suitable for many applications, such as pressure tubes in the primary loops of some reactors. Furthermore, the corrosion resistance of the Zr-2.5Nb alloy can be substantially improved by heat treatments.<sup>42,43</sup> In addition, the Zr-2.5Nb alloy is superior to Zircaloys in steam at temperatures above 400 °C.<sup>43</sup>

#### 3.14.3.2 Other Aqueous Systems

##### 3.14.3.2.1 Cooling waters

Unalloyed zirconium does not seem to have irregular behavior in cooling waters, such as the towns water, river water, or potable water, that are used as the

cooling media in the chemical process industry. Such waters have much higher levels of impurities than water used in the nuclear reactors. The highest temperature in such heat exchangers is around 300 °C, and the longest lifetime is more than 20 years; zirconium has generally performed well in these waters.

The major difference between pure water in nuclear reactors and common cooling waters is their corrosivity. There is also the important factor of the effect of neutron flux on the oxidation process, which is likely to accelerate corrosion by increasing lattice diffusion. However, in the chemical process industry zirconium heat exchangers can have a long and satisfactory life. For example, two zirconium heat exchangers were retired from a urea plant after continual service for 20 years. The tubes looked like new and were used to build yet another heat exchanger. The watersides of the tubes were covered with very thin oxide films without any sign of breakaway oxidation after 20 year's use.

### 3.14.3.2.2 Salt solutions

Zirconium has excellent corrosion resistance to seawater, brackish water, and polluted water. Zirconium's advantages in salt waters include its insensitivity to variation in factors like chloride concentration, pH, temperature, velocity, crevice, and sulfur-containing organisms. The effects of pH on iron-ions-containing salt water were discussed earlier. Results of certain field and laboratory tests are summarized as follows.<sup>28</sup>

Zr702 specimens with or without a crevice attachment were placed in the Pacific Ocean at Newport, OR, for up to 129 days. All welded and nonwelded specimens exhibited nil corrosion rates. Marine biofouling was observed; however, no attack was found beneath the marine organisms or within the crevices. Laboratory tests were performed on specimens of Zr702 and Zr704 in boiling seawater for 275 days and in 200 °C pressurized seawater for 29 days. Both alloys resisted general corrosion, pitting, and crevice corrosion.

U-bend specimens, with or without steel coupling, of Zr702, nickel-containing Zr704 or zircaloy-2, and nickel-free Zr704 or zircaloy-4, were tested in boiling seawater for 365 days as shown in Table 7. No cracking was observed during the test period. Overstressing of the tested U-bends indicated that all specimens, except one, remained ductile. The exception was the welded nickel-containing Zr704 with steel coupling which showed some hydrogen and oxygen absorption. Chemical analyses and metallographic examinations on other U-bends did not reveal any evidence of hydrogen absorption and

**Table 7** Chemical analyses for hydrogen and oxygen (ppm) of tested U-bends in boiling seawater for 365 days

<i>Metal</i>	<i>Hydrogen</i>	<i>Oxygen</i>
Nonwelded Zr702 U bend with steel coupling	6	1350
Nonwelded Zr704 (Ni-containing) U bend with steel coupling	8	1480
Nonwelded Zr704 (Ni-free) U bend with steel coupling	9	1440
Welded Zr702 U bend with steel coupling	8	1250
Welded Zr704 U bend (Ni-containing) with steel coupling	450	5000
Welded Zr704 (Ni-free) U bend with steel coupling	5	1480

hydride formation. Results of chemical analyses are given in. These results support that the presence of nickel in zirconium promotes hydrogen pick-up.

Zirconium resists most salt solutions, which include halogen, nitrate, carbonate, and sulfate.<sup>59,60</sup> Corrosion rates are typically very low at temperatures at least up to the boiling point. Solutions of strong oxidizing chloride salts, such as ferric and cupric chlorides, are examples of the few exceptions. Zirconium is considerably more resistant to chloride SCC than are stainless steels.<sup>32</sup> For example, U-bends of Zr702 do not fail in boiling 42% magnesium chloride. Another attractive property of zirconium is its high resistance to crevice corrosion. Zirconium is not subject to crevice corrosion even in acidic chloride solutions at elevated temperatures. No attack was observed on zirconium in a salt spray environment.<sup>67</sup>

### 3.14.3.2.3 Sulfur compounds

Sulfur and its compounds are highly corrosive to common metals. They are often present in underground fluids, such as oil, natural gas, and geothermal fluids. Though zirconium is a reactive metal, it has little affinity for sulfur. Consequently, zirconium has excellent corrosion resistance to sulfur and its compounds. It requires a high temperature, around 700–900 °C, for zirconium to react with sulfur vapor or hydrogen sulfide to yield a number of sulfides. Moreover, there is no instance of zirconium–sulfur bonds forming in aqueous systems.<sup>44,45</sup> Practically, therefore, zirconium is immune to sulfide stress cracking (SSC).

### 3.14.3.3 Inorganic Acids

#### 3.14.3.3.1 Sulfuric acid

Sulfuric acid is the most important acid for use in the manufacture of many chemicals. For example, the

acid is used as a dehydrating agent, an oxidizing agent, an absorbent, a catalyst, a reagent in chemical syntheses, and much more. These highly versatile capabilities can be attributed to the complicated nature of this acid. Sulfuric acid is a corrosive with a continuously changing character. It changes from the reducing nature of dilute acid to the oxidizing nature of concentrated acid. The reactivity of sulfur compounds and the difficulty of forming protective oxide films under reducing condition make common passive metals vulnerable to corrosion in dilute acid. In fact, hot, dilute acid is a pickling solution for steel and stainless steel. Solutions become increasingly oxidizing at or above 65%. The usefulness of passive metals and alloys depends strongly on acid concentration, temperature, aeration, and other impurities.

Zirconium and its alloys are straightforward in their corrosion resistance to sulfuric acid as shown in **Figures 13–15**.<sup>48</sup> Published data for zirconium before the establishment of Zr702 were collected to construct **Figure 13(a)**. Corrosion data generated at the Wah Chang company were used to construct **Figures 13(b), 14, and 15** for ASTM grades. It should be noted that isocorrosion curves are normally constructed based on short-term results of laboratory tests conducted under well-controlled conditions. The curves should be used to understand the corrosion behavior of the alloys rather than to predict the performance of the alloys in actual service. There are many factors affecting the performance of the alloys. The factors include impurities in the alloys and environments, equipment design and fabrication, operating conditions, and maintenance.

Zirconium and its alloys resist attack by sulfuric acid at all concentrations up to 70%. The major difference among these grades is in the near boiling region when the acid concentration is greater than 60%. In this region, Zr702 outperforms Zr704 and Zr705. In 70–80% sulfuric acid, the corrosion resistance of zirconium and its alloys depends strongly on temperature. In higher concentrations, the corrosion rate of zirconium and its alloys increases rapidly with concentration due to the formation of nonprotective zirconium sulfate film.

There are three regions in **Figure 13(a)** that are attractive for using zirconium in sulfuric acid services. The first region is dilute sulfuric acid,  $\leq 10\%$ , at elevated temperatures. In this region, the temperature limit for zirconium is well above 200 °C. The second region is hot 10–45% sulfuric acid, where zirconium is highly stable in the passive state. Zirconium can tolerate lots of oxidizing impurities and some chlorides. The third region is 45–70% sulfuric acid where

zirconium stays corrosion resistant when factors like acid concentration and impurities are controlled within zirconium's limitations.

The corrosion behavior of zirconium can be further examined from electrochemical measurements. The anodic polarization curves of zirconium in 4.9–72.5% sulfuric acid at near-boiling temperatures are shown in **Figure 16**. As indicated in **Figure 16**, zirconium experiences a passive-to-transpassive transition in sulfuric acid with an increasing potential. Zirconium does not have the active region in sulfuric acid as is the case with common metals and alloys.

As indicated in **Figure 16**, zirconium has very high transpassive (breakdown) potentials in dilute sulfuric acid. This indicates that zirconium can tolerate large amounts of oxidizing agents, such as ferric and nitrate ions in dilute sulfuric acid. For example, there is no effect on zirconium in steel pickling application even after a few percent of iron dissolves in dilute sulfuric acid, provided that chlorides are not present in significant amounts.

In  $>20\%$  sulfuric acid, the breakdown potential of zirconium decreases noticeably with increasing concentration. Looking at **Figure 16** closely, still there is a visible passive region for zirconium in 65% sulfuric acid. This means zirconium can tolerate some amounts of strong oxidizing agents in  $\leq 65\%$  sulfuric acid.<sup>47</sup> In  $>65\%$  sulfuric acid, zirconium becomes sensitive to the presence of oxidizing agents. **Figure 17** illustrates the effect of the presence of 200 ppm of various oxidizing agents on zirconium in  $>65\%$  sulfuric acid.

The acid concentration limit is very important when zirconium is used to process sulfuric acid in the marginal concentration region, such as 60% or more. In less than 65% sulfuric acid, although the vapor is almost entirely water, the concentration shows little change in a pressurized system. However, acid concentration can change significantly because, for example, of the imperfect sealing of a system. Acid concentration can easily change in a vacuum system because the water vapor is continuously removed.

When the acid concentration limit is exceeded, zirconium may corrode rapidly. Under certain conditions, a pyrophoric surface layer may be formed on zirconium. The pyrophoric surface layer on zirconium formed in 77.5% sulfuric acid + 200 ppm ferric ion at 80 °C consisted of  $\gamma$ -hydride, zirconium sulfate, and fine metallic particles. The combination of  $\gamma$ -hydride and metallic particles is suggested to be responsible for the pyrophoricity.<sup>48</sup> Treating in hot steam can be used to eliminate this tendency.

As shown in **Figures 13(b), 14, and 15**, the resistance of zirconium in  $>55\%$  sulfuric acid is

**Figure 13** The isocorrosion diagram of (a) zirconium in sulfuric acid and (b) Zr702 in sulfuric acid.

somewhat degraded resulting from welding. Zirconium weld metal may corrode preferentially and can be attributed to the morphology of the second-phase particles as previously discussed. Heat treatment at

$775 \pm 15^\circ\text{C}$  for 1 h per 25 mm of thickness can be used to restore the corrosion resistance of weld metal.

The presence of chlorides in sulfuric acid does not degrade zirconium's resistance unless oxidizing ions

**Figure 14** The isocorrosion diagram of Zr704 in sulfuric acid.

are also present. When heavy metal ions and halide ions coexist in sulfuric acid, the optimum acid concentration range for zirconium is 60–65%. Sulfate ion possesses a mild inhibitive effect on the pitting of zirconium in chloride solutions. In  $\leq 1\%$  chloride solution, a minimum  $[\text{SO}_4^{2-}]/[\text{Cl}^-]$  ratio of  $\geq 42$  is needed for inhibition.<sup>20</sup> The more sulfate ions in the solution, the more oxidizing ion zirconium can tolerate before pitting occurs. **Figure 18** can be used as a guide when chloride ions and oxidizing ions coexist.

#### 3.14.3.3.2 Halogen acids

Zirconium resists attack by most halides, including halogen acids. Exceptions include hydrofluoric acid and oxidizing chloride solutions. It has been discussed that surface condition greatly affects the corrosion of zirconium in oxidizing chloride solutions. Zirconium has some corrosion resistance in certain fluorides when the pH is high enough. For example, small amounts of fluorides in city or ground water have little effect on zirconium's corrosion resistance. However, a few ppm hydrofluoric acid will noticeably increase the general

corrosion of zirconium. Nevertheless, zirconium and its alloys have very limited usefulness in fluoride-containing solutions. The concern is general corrosion but not pitting. Zirconium and its alloys exhibit low corrosion rates in fluoride solutions only when the temperature is low enough, and the pH is high enough. They are totally defenseless in HF-containing solutions. At room temperature, hydrofluoric acid exists when the pH is less than 3.18. The effect of pH on the corrosion of zirconium in fluoride-containing solutions is shown in **Table 8**.<sup>49</sup>

It should be noted that there are overlooked sources for fluorides.<sup>21,22</sup> Overlooked sources include recycled chemicals and PTFE. For example, recycled sulfuric acid may contain more than 100 ppm fluoride ions.<sup>21</sup> When zirconium equipment faces fluoride-containing acids, inhibitors that form strong fluoride complexes should be added for protection.<sup>21</sup> Useful inhibitors include zirconium sponge, soluble zirconium chemicals, and phosphorous pentoxide. **Table 9** gives results of the effects of certain inhibitors on zirconium's corrosion in fluoride-containing solutions.

**Figure 15** The isocorrosion diagram of Zr705 in sulfuric acid.

**Figure 16** Anodic polarization curves for Zr702 in sulfuric acid at near boiling temperature.

**Figure 17** Effect of various oxidizing ions on the 0.125-mm year<sup>-1</sup> isocorrosion line for Zr702 in sulfuric acid.

**Figure 18** Chloride allowable for Zr702 in sulfuric acid in oxidizing condition.

Unlike titanium and tantalum, the corrosion resistance of zirconium in halides increases in the order of chloride, bromide, and iodide. Unless the condition is oxidizing, zirconium is very corrosion resistant in chloride solutions, including strong hydrochloric acid. Oxidizing conditions include the presence of oxidizing agents, coupling with a noble material,

and applied anodic potential. In the absence of oxidizing conditions, zirconium is one of the most corrosion resistant metals to hydrochloric acid. As shown in [Figure 19](#), zirconium is totally resistant to attack in all concentrations of hydrochloric acid. Normally, stainless alloys can be considered only for handling very dilute and/or low-temperature hydrochloric

acid. Zirconium would outperform stainless alloys in hydrochloric acid. Moreover, zirconium is not as susceptible to hydrogen embrittlement in hydrochloric acid as tantalum.

Although hydrochloric acid is strongly reducing, the anodic polarization curves of zirconium still do not have an active region as exhibited in [Figure 20](#). However, [Figure 20](#) shows that zirconium may suffer pitting and/or SCC when it is anodically polarized to a potential at or exceeding the pitting potentials. The same types of corrosion problems can be developed in hydrochloric acid when strong oxidizing agents are present. [Figure 21](#) illustrates the detrimental effect of ferric ions in 20% HCl at 100 °C. The presence of ferric ions polarizes the zirconium surface to a potential exceeding the pitting potential. Thus, local breakdown of the passive surface at preferred sites occurs, and a condition develops that favors pitting and/or SCC. Maintaining zirconium at a potential in

its passive region, which is arbitrarily set at 50–100 mV below the corrosion potential, can counteract the detrimental effects resulting from the presence of ferric ions.

### 3.14.3.3.3 Nitric acid

Because of its passivating power, nitric acid is considered to be compatible with passive alloys. However, nitric acid becomes highly corrosive when its temperature is high or when impurities, such as heavy-metal ions, are present. The passivating power favors the formation of oxide films but may also cause the passive films to break down.

Zirconium is considerably more suitable than most passive alloys for handling nitric acid, particularly when the acid is hot, impure, and/or variable in concentration. The excellent corrosion resistance of zirconium in nitric acid has been recognized for more than 30 years.<sup>50–52</sup> Below the boiling point and at 98% nitric acid, and up to 250 °C and at 70% nitric

**Figure 19** The isocorrosion diagram of Zr702 in hydrochloric acid.

acid, the corrosion rate of zirconium is less than  $0.13 \text{ mm year}^{-1}$  as shown in [Figure 22](#).

Zirconium is normally susceptible to pitting in acidic oxidizing chloride solutions. However, nitrate ion is also an inhibitor for the pitting of zirconium because of its passivating power. The minimum  $[\text{NO}_3^-]/[\text{Cl}^-]$  molar ratio required to inhibit pitting of zirconium is between 1<sup>30,51,52</sup> and 5.<sup>53</sup> Results of tests indicate that zirconium's resistance is not degraded in up to 70% nitric acid with dissolved 1% ferric chloride, 1% sodium chloride, 1% seawater, 1% ferric ion, or 1% stainless steel at 204 °C.<sup>54</sup> Still, the presence of an appreciable amount of HCl should be avoided since zirconium is not resistant to aqua regia.

The polarization curves of zirconium in nitric acid are shown in [Figure 23](#). Again, zirconium has the passive-to-transpassive transition similar to that which occurs in sulfuric acid. However, corrosion potentials are noble because of the oxidizing nature of nitric acid. As indicated in the above test results, common oxidizing agents, such as ferric ions, do not affect the corrosion resistance of zirconium in nitric acid. The polarization curves do suggest that, zirconium may be susceptible to SCC in concentrated nitric acid. This is shown by the low passive-to-transpassive potential. This is consistent with the observation of SCC in U-bend specimens in greater than 70% nitric acid.<sup>55</sup> The slow strain-rate technique reveals zirconium's susceptibility to SCC in less than 70% nitric acid.<sup>56</sup> Results of C-ring tests indicate that zirconium specimens will have a long

life when they are stressed below the yield point.<sup>55</sup> Avoiding high-sustained tensile stresses is effective in controlling the SCC of zirconium.<sup>57</sup>

Additional concerns include the accumulation of chlorine gas in the vapor phase and the presence of fluorides. Chlorine gas may be generated by the oxidation of chlorides by nitric acid. Areas that can trap chlorine gas should be avoided for zirconium equipment when chlorides are present in nitric acid. Fluorinated materials should be carefully applied and may be overlooked sources for fluorides.

#### 3.14.3.3.4 Phosphoric acid

Phosphoric acid is less corrosive than other mineral acids. Many materials demonstrate useful resistance in phosphoric acid at least at low temperatures. Corrosion rates often increase with temperature and impurities in the acid. [Figure 24](#) shows that zirconium resists attack in phosphoric acid at concentrations up to 55% and temperatures exceeding the boiling point. Above 55% phosphoric acid, the corrosion rate of zirconium increases with temperature. The most interesting area for zirconium would be dilute acid at elevated temperatures. [Figure 25](#) gives the anodic polarization curves of zirconium in phosphoric acid at near-boiling temperatures. As concentration increases, the passive range diminishes gradually, and the passive current increases progressively. It appears that zirconium passivates more slowly in phosphoric acid than in other mineral acids.

If phosphoric acid contains more than a trace of fluoride ions, attack on zirconium may occur. Because

**Figure 22** The isocorrosion diagram of Zr702 in nitric acid.

**Figure 23** Anodic polarization curves for Zr702 in nitric acid at near boiling temperature.

fluoride compounds are often present in phosphoric acid, the acid specification is important when zirconium equipment is involved. For example, food grades contain little fluoride ion, while technical grades may contain tens to thousands ppm fluoride ions.

#### 3.14.3.3.5 Other inorganic acids

Zirconium resists chromic acid up to 30% at temperatures to 100 °C<sup>58</sup> but it is not suitable for handling certain chrome-plating solutions that contain fluoride catalysts. Zirconium is also resistant to certain mixed acids that include sulfuric–nitric, sulfuric–hydrochloric, and phosphoric–nitric mixtures. The sulfuric acid concentration must be below 70%.<sup>51,52,59,60</sup> Zirconium is aggressively attacked in 1:3 volume mixtures of nitric and hydrochloric acids (aqua regia). In the volume mixture, zirconium is attacked more slowly than in the aqua regia.<sup>51,52</sup> In mixtures greater than the 3:1 ratio, zirconium becomes resistant. Data for some mixed acid systems are given in [Table 10](#).

**Figure 24** The isocorrosion diagram of Zr702 in phosphoric acid.

### 3.14.3.4 Other Aqueous Environments

#### 3.14.3.4.1 Hydrogen peroxide

Hydrogen peroxide is a unique and most important covalent peroxide. Many of its physical properties resemble those of water. However, chemically, it is very much different from water. It is not as stable as water. It decomposes into water and oxygen upon heating or in the presence of numerous catalysts, particularly salts of such metals as iron, copper, manganese, nickel, or chromium. Explosion may occur resulting from catalytic decomposition. Often small amounts of stabilizers, for example, tin salts and phosphates, are needed to suppress peroxide decomposition.

Hydrogen peroxide can be corrosive even to highly corrosion resistant metals and alloys such as titanium. In fact, titanium is one of the worst materials for handling hydrogen peroxide solutions. One reason is that hydrogen peroxide has the capability of forming peroxide complex compounds by attacking metals and alloys. These compounds may be soluble and are not as protective as oxide films.

Zirconium is regarded as one of the best materials for hydrogen peroxide service.<sup>61,62</sup> Its corrosion resistance in this medium is excellent. It does not produce active ions to catalytically decompose hydrogen peroxide. It has few problems for use in the production of hydrogen peroxide since it is essential to keep impurities out of process streams.

Nevertheless, zirconium is susceptible to pitting in oxidizing chloride solutions, and hydrogen peroxide is an oxidizer. Zirconium may pit in hydrogen peroxide solutions even when drops of hydrochloric acid are added for acidification.<sup>63</sup> It should be noted that zirconium is fully compatible with other acidic peroxide solutions when acids such as sulfuric acid are added.

#### 3.14.3.4.2 Alkaline solutions

Zirconium resists attack in most alkalis, which include sodium hydroxide, potassium hydroxide, calcium hydroxide, and ammonium hydroxide.<sup>58,64,65</sup> This makes zirconium distinctly different from some other high performance materials, such as titanium, tantalum, glass, graphite, and PTFE, which are attacked by strong alkaline solutions.

U-bends of Zr702 were tested in boiling 50% sodium hydroxide. During the test period, the concentration changed from 50% to about 85%, and temperature increased from 150 to 300 °C. The PTFE washers and tubes used to make the U-bends dissolved. However, the zirconium U-bends remained ductile and did not show any cracks after 20 days.

Coupons of Zr702 were tested in white liquor, paper-pulping solution, which contains sodium hydroxide and sodium sulfide, at 125, 175, and 225 °C. All coupons had corrosion rates of less than

0.025 mm year<sup>-1</sup>. In the same solution, graphite and glass both corroded at 100 °C. Zr702 also exhibited resistance to SCC in simulated white liquor.<sup>66</sup>

#### 3.14.3.4.3 Urea

Zirconium has been recognized as the most corrosion-resistant metal for urea-synthesis service.<sup>68,69</sup> Stainless alloys corrode in urea-synthesis conditions at rates exceeding 2 mm year<sup>-1</sup>.<sup>68</sup> Even silver has a high corrosion rate at 0.76 mm year<sup>-1</sup>. Although titanium does not corrode much, it exhibits several problems, such as erosion<sup>69</sup> and hydrogen embrittlement.<sup>70</sup>

One of the earliest applications of zirconium was in the production of urea. Certain zirconium vessels and heat exchangers have been in service for more than 30 years and show no signs of corrosion. However, the high corrosion rates of stainless steels are greatly reduced when oxygen is added to the process stream. Oxygen or air injection has become popular as the corrosion control measure in urea plants. The advantage of zirconium has been overlooked for many years.

In recent years, zirconium is making a comeback. The driving force for the renewed interest in zirconium is the concern about the presence of heavy metals in fertilizers. Stainless steel equipment still corrodes somewhat even with the oxygen injection measure. To protect the environment, permissible levels for the presence of heavy metal salts in fertilizers are being tightened. The corrosion resistance and nontoxicity of zirconium cannot be ignored in achieving new environmental standards.

#### 3.14.3.5 Organic Acids

##### 3.14.3.5.1 Acetic acid

The importance of acetic acid in the organic chemistry industry is comparable to that of sulfuric acid in the inorganic chemistry industry. Acetic acid can effectively acidify aqueous solutions, increasing their corrosivity. It is not highly corrosive at low temperatures. Many materials, including wood, rubber, aluminum, copper, stainless steels, and titanium, have been used in acetic acid service with different degrees of success. Corrosion problems arise due to variations in acid concentration, temperature, solution impurities or catalysts, and heat transfer.<sup>71</sup>

For over 40 years, zirconium has been recognized as one of the most versatile materials for acetic acid service.<sup>71-74</sup> Zirconium shows nil corrosion rates (<0.025 mm year<sup>-1</sup>) in most acetic acid media at temperatures up to at least 260 °C. In fact, acetate ions have a mildly inhibitive effect on the localized

corrosion of zirconium in halide solutions. Conditions that lead to corrosion are few. They include very dry acid (<650 ppm water) and the presence of copper ions in the acid.<sup>75</sup>

Zirconium has become an important material for the production of acetic acid through the reaction of methanol and carbon monoxide. This technology has been studied for more than 40 years. It could be commercialized in the 1970s only when the corrosion problems of structural materials were managed. In this technology, the reaction must proceed at a high temperature (at or greater than 150 °C) and a high pressure (3.3–6.6 MPa) in the presence of a halide as the catalyst. Process equipment must be made of highly corrosion-resistant materials. Zr702 and Zr705 are often used to construct process equipment, such as reactors, columns, heat exchangers, pumps, valves, piping systems, trays, and packings.

When various alloys were evaluated in acetic acid environments, zirconium was identified as the most corrosion resistant.<sup>72,73</sup> Nevertheless, in certain tests, zirconium exhibited pitting and high corrosion rates in mixtures of acetic acid and acetic anhydride when copper ions were present. Copper ions seem to play a catalytic role in the corrosion process. It is undesirable, therefore, for zirconium equipment to be exposed to acetic acid contaminated with copper ions. Copper ions may come from corrosion of upstream equipment made of copper-containing alloys and may also be added as catalysts in certain processes.

##### 3.14.3.5.2 Formic acid

Formic acid is more easily ionized than acetic acid. Therefore, formic acid is expected to be more corrosive than acetic acid. Indeed, formic acid attacks many common metals and alloys. Steel corrodes rapidly in this acid at all concentrations, even at ambient temperatures. Stainless alloys have some serious limitations. Type 304 stainless steel resists only 1–2% formic acid at boiling. Type 316 stainless steel is attacked by hot formic acid in the intermediate concentrations. Nickel-based alloys may corrode at high rates in the acid with the presence of certain impurities like halides and under heat-transfer conditions. Titanium and its alloys are not consistent due to factors such as aeration and water content. Compared to the mentioned alloys, zirconium is versatile and corrosion resistant in most formic acid solutions.<sup>76</sup>

Zirconium has played a key role in the commercialization of the Leonard–Kemira process.<sup>77,78</sup> In this process, CO gas contacts methanol in the presence of a catalyst to form methyl formate in a reactor.

The methyl formate is hydrolyzed in the presence of a catalyst to yield formic acid and methanol, which are separated by distillation. The methanol is recycled in the first stage of the process. Factors such as elevated temperatures and pressures and the presence of water and catalyst make common materials, including glass lining, resin and plastic coatings, and stainless alloys inadequate as structural materials for this process. Zirconium proves to be the most economical structural material for use in the main equipment for this process.

### 3.14.3.6 Other Organic Environments

Zirconium has excellent corrosion resistance in most organic environments. Exceptions are certain halide-containing organic solutions (e.g., impure methanol) and organic halides (e.g., dichloroacetic and trichloroacetic acids). Zirconium has been extensively tested in organic-cooled reactors where the coolant consists of mixtures of high-boiling aromatic hydrocarbons, for example, terphenyls.<sup>79</sup> These coolants are non-corrosive to zirconium. However, early experiments in the organic coolants indicated that hydriding was a major concern. It was found that chlorine as an impurity in the coolants was the reason for hydriding. Elimination of the chlorine and maintenance of a good surface oxide film by ensuring the presence of some water (>50 ppm) alleviates the hydriding problem. Indeed, the combination of a lack of water and the presence of halogens or halides is the common reason for zirconium to corrode in organic environments. For example, addition of some water suppresses zirconium's susceptibility to SCC in alcohol solutions with halides.<sup>80-82</sup>

On the one hand, zirconium shows excellent corrosion resistance in many chlorinated carbon compounds, such as carbon tetrachloride and dichlorobenzene at temperatures up to 200°C. On the other hand, zirconium is poor in certain chlorinated organic chemicals, such as acetyl halides, even at ambient temperatures. It is well known that certain organic halides are very corrosive to metals in the absence of water and oxygen. Metals can directly incorporate into these compounds to form intermetallic compounds. The reactions were investigated extensively by Grignard during the early 1900s. Today, organometallic halides are termed 'Grignard' reagents. Unsaturated organic compounds and alkyl, aryl, and vinyl halides are commonly used to react with metals in the preparation of organometallic compounds. They are potentially corrosive to metals, including zirconium. From the corrosion

point of view, organic halides can be classified into three groups, that is, water soluble, water insoluble, and water incompatible.

Water-soluble halides, such as aniline hydrochloride, chloroacetic acid, and tetrachloroethane, are not corrosive to zirconium. More active halides, such as dichloroacetic and trichloroacetic acids, are corrosive to zirconium. Corrosion rates of zirconium in these two acids at boiling are greater than 500 and 1250  $\mu\text{m year}^{-1}$  respectively. Water addition and stress relieving could be effective in controlling the corrosion of zirconium in water-soluble halides. Water-insoluble halides, such as trichloroethylene and dichlorobenzene, are not corrosive to zirconium, which is to be expected because of their stability. They do not dissolve in water, and they can be physically mixed together with water. Water-incompatible halides, such as acetyl chloride, may be highly corrosive to zirconium. They are not just unstable, but also react violently with water. There is no chance for water to be present in this type of halides, which are the most undesirable organic compounds for zirconium to handle.

## 3.14.4 High Temperature Degradation

### 3.14.4.1 Oxidation and Hot Corrosion

Zirconium forms a visible oxide film in air at about 200°C. The oxidation rate becomes high enough to produce a loose, white scale on zirconium at temperatures above 540°C. At temperatures above 700°C, zirconium can absorb oxygen and become embrittled after prolonged exposure.

Zirconium reacts more slowly with nitrogen than with oxygen since it has a higher affinity for oxygen than for nitrogen. Also, a layer of oxide film normally protects zirconium from reacting with nitrogen. However, once nitrogen penetrates through the oxide layer, it diffuses into the metal faster than oxygen. Clean zirconium starts the nitriding reaction in ultrapure nitrogen at about 900°C. Temperatures of 1300°C are needed to fully nitride zirconium. The nitriding rate can be enhanced by the presence of oxygen in the nitrogen or on the metal surface.

The oxide film on zirconium provides an effective barrier to hydrogen absorption up to 760°C, provided that small amounts of oxygen are also present in hydrogen for healing damaged spots in the oxide film. In an all-hydrogen atmosphere, hydrogen absorption will begin at a much lower temperature,

that is, 310 °C. Zirconium will ultimately become embrittled by forming zirconium hydrides. Hydrogen can be removed from zirconium by prolonged vacuum annealing at temperatures above 760 °C.

The corrosion and oxidation of zirconium and its alloys in steam are of special interest to nuclear power applications. The alloys can be exposed for prolonged period without pronounced attack at temperatures up to 425 °C. In the 360 °C steam, up to 350 ppm chloride and iodide ions, 100 ppm fluoride ions, and 10 000 ppm sulfate ions are acceptable for zirconium in general applications but not in nuclear power applications.

Zirconium is stable in ammonia up to about 1000 °C, in most gases (carbon monoxide, carbon dioxide, and sulfur dioxide) up to about 300–400 °C, and in dry halogens up to about 200 °C. At elevated temperatures, zirconium forms volatile halides. The corrosion resistance of zirconium in wet chlorine depends on surface condition. Zirconium is susceptible to pitting in wet chlorine unless it has been properly cleaned.

#### 3.14.4.2 Molten Salts and Metals

Zirconium resists attack in some molten salts. It is very resistant to corrosion by molten sodium hydroxide to temperatures above 1000 °C and is also fairly resistant to potassium hydroxide. The oxidation properties of zirconium in nitrate salts are similar to those in air. Zirconium also resists some types of molten metals, but the corrosion resistance is affected by trace impurities such as oxygen, hydrogen, or nitrogen.<sup>83</sup> It has a corrosion rate less than 25  $\mu\text{m year}^{-1}$  in liquid lead to 600 °C, lithium to 800 °C, mercury to 100 °C, and sodium to 600 °C. The molten metals known to attack zirconium include aluminum, zinc, bismuth, and magnesium.

### 3.14.5 Corrosion Protection

#### 3.14.5.1 Protective Film Formation

Zirconium oxide, which forms on zirconium's surface, is among the most insoluble compounds in a broad range of corrosives. This film, although very thin, provides excellent protection for zirconium from corrosion in most media. When the film is mechanically damaged, it will regenerate itself. For corrosion resistance, there is no need to thicken the film before zirconium equipment is placed in a corrosive medium. However, it is desirable to preoxidize

zirconium for meeting heavy mechanical duties. Properly oxidized zirconium has a much-improved performance against sliding forces, although it can be damaged by striking action. Oxidized zirconium pump shafts are an example of common applications. Bolts and nuts are often oxidized for the purpose of preventing galling. Several methods for forming thick layers of oxide films are available. They include anodizing, autoclaving in hot water or steam, oxidation in air or oxygen, and formation in molten salts.

Anodizing forms a very thin film ( $<0.5 \mu\text{m}$ ). The surface of zirconium with anodized films appears in different colors that vary through the entire spectrum. The thickness of the film is in the range of the wavelengths of visible light. Consequently, because of interference of this light, only certain wavelengths are selectively reflected through the film from the zirconium metal underneath. Nevertheless, the film is formed at ambient temperatures and does not adhere to the underlying metal as well as thermally produced films. Anodized films may look beautiful but have very limited capability to protect the metal from mechanical damage.

Autoclaving in hot water or steam is a common practice for determining 'corrosion resistance' in the nuclear industry. In this method, the uniform film of high integrity is formed in pressurized (19 MPa) deionized water at 360 °C for 14 days or in high purity steam (10 MPa) at 400 °C for 1–3 days. In addition to improving corrosion resistance, the rate of hydrogen absorption is greatly reduced.

Oxidation in air or oxygen under well-controlled conditions can produce high quality films on zirconium. The formed films serve as an excellent bearing surface against a variety of materials. For example, a layer of black film forms on a cleaned zirconium component in air at 550 °C for 4–6 h<sup>84</sup> or in a fluidized bed using oxygen during the oxide formation period but using an inert gas during the heating and cooling periods.<sup>85</sup> The resultant oxide layer is approximately 5 and 20  $\mu\text{m}$ , respectively. It is equivalent to sapphire in hardness and is diffusion bonded to the base metal. The oxide layer can be damaged by a striking force, but it serves as an excellent surface for sliding contact.

Film formation in molten salts is useful for small components. In this process, a zirconium subject is treated in fused sodium cyanide containing 1–3% sodium carbonate, or in a eutectic mixture of sodium and potassium chlorides with 5% sodium carbonate.<sup>86</sup> Treatment is carried out at a temperature ranging from 600 to 800 °C for up to 50 h. The thickness of

oxide film formed by this method is 20–30  $\mu\text{m}$ . This film greatly improves resistance to abrasion and galling over thick oxide films grown by many other methods.

### 3.14.5.2 Surface Conditioning

**Figure 11** shows the effect of surface condition on the rest potential of zirconium in 10% HCl + 500 ppm  $\text{Fe}^{3+}$  at 30 °C. Air annealing yields rest potentials nobler than the pitting potential,  $E_{\text{crit}}$ , due to the formed thick oxide during annealing. This does not mean that pitting will occur if the film quality is good. This does put thick oxide coated materials in a position vulnerable to pitting, particularly when there is an anodically applied potential. Surfaces abraded with either 600 grit SiC or  $\text{Al}_2\text{O}_3$  cloth reach the pitting potential quickly and have short pit initiation times. This can be attributed to the presence of embedded particles resulting from rough polishing. Pickled and finely polished surfaces have rest potentials below the pitting potential. They are very resistant to pitting even in oxidizing chloride solutions. This can be attributed to surface homogeneity that favors general corrosion but not localized corrosion. Results of immersion tests indicate that pickled zirconium performs well in boiling 10%  $\text{FeCl}_3$  and in  $\text{ClO}_2$ .<sup>20,87</sup> It is well known that zirconium with a normal surface finish is unsuitable for handling these solutions.

### 3.14.5.3 Electrochemical Protection

Zirconium exhibits a passive-to-transpassive transition with increasing potential in all mineral acids except hydrofluoric acid.<sup>88</sup> The commonly observed active node, as shown in **Figure 8** for many metal–acid systems, is not observed for zirconium. Consequently, zirconium performs well in most reducing media. This can be attributed to zirconium's ability to take oxygen from water to form a stable passive film.

Most passive alloys would need some oxidizing agent, such as the presence of oxygen, for them to form passive films. In fact, zirconium is one of the best metals for handling reducing media. On the other hand, zirconium may experience corrosion problems, such as pitting and SCC, under oxidizing conditions. These problems can be controlled by converting the oxidizing condition to a more reducing condition by various means.

Potentiostatically, by impressing a potential that is arbitrarily 50–100 mV below its corrosion potential, zirconium becomes corrosion resistant in oxidizing chloride solutions.<sup>89</sup> **Tables 11 and 12** demonstrate the benefits of electrochemical protection in controlling pitting and SCC. **Table 11** shows that the general corrosion rates of unprotected zirconium in oxidizing chloride solutions may be low. However, the penetration rates are much higher than the general corrosion rate. Electrochemical protection eliminates this local attack. As indicated in **Table 12**, unprotected U bends of welded zirconium cracked in all but one case shortly after exposure. Protected U bends resisted cracking for the 32-day test interval in all but one acid concentration. Thus, electrochemical protection offers an improvement to the corrosion properties of zirconium in oxidizing chloride solutions.

This technique is also applicable to control the SCC of zirconium in concentrated nitric acid.<sup>57</sup> Because of the strong oxidizing power of the acid, zirconium exhibits a noble corrosion potential. Also, there is a large difference between the corrosion potential and the critical potential to cause SCC. It is desirable to control the potential of zirconium a few hundred millivolts below the corrosion potential or at 740 mV NHE.

### 3.14.5.4 Other Measures

Ferric and cupric ions are the common oxidizing agents experienced in the CPI. Cupric ion is more

detrimental than ferric ion in promoting the general corrosion and pitting of zirconium in acidic chloride solutions. **Tables 13 and 14** demonstrate the effect of pH, welding, and heat treatment on the corrosion of zirconium in cupric ion-containing solutions. The corrosion problems of zirconium in these solutions can be controlled by adjusting the pH to 6 or higher (**Table 13**) or by high temperature heat treatment (**Table 14**). In ferric ion-containing solutions, it is sufficient to adjust the pH to 3 or higher.

Various inhibitors, such as nitrate, sulfate, and stannous ions, can be used to control the pitting of zirconium in chloride solutions.<sup>20</sup> Furthermore, the solution potential of an oxidizing solution can be lowered when a small amount of hydrofluoric acid is added.<sup>20,57</sup> Therefore, hydrofluoric acid can be used to control pitting and SCC of zirconium in

<sup>a</sup>Pitting AC, air-cooled; WQ, water-quenched.

oxidizing solutions, such as concentrated nitric acid and ferric chloride solutions. Since hydrofluoric acid is very corrosive to zirconium, the corrosivity of this acid can be neutralized by adding a complexing agent, such as zirconium sponge or zirconium compounds.

Tensile stresses provide a driving force for not just SCC but also for other types of corrosion to occur. Lowering residual stresses by a stress-relieving treatment is useful in controlling pitting as well.

### 3.14.6 Industrial Applications

For more than 40 years, many corrosive applications have been developed for zirconium and its alloys. Zirconium and its alloys are being used as structural materials in fabricating columns, reactors, heat exchangers, vaporizers, pumps, piping systems, valves, and agitators for the chemical process industry. The chemical process industry recognized the advantages of zirconium for solving corrosion problems from zirconium's inception.

#### 3.14.6.1 Processes Using Sulfuric Acid

Zirconium is used for the manufacture of  $\text{H}_2\text{O}_2$  by the electrolysis of acid sulfates. This production process is extremely corrosive and, at one time, graphite equipment was standard for this process. FMC's plant in Vancouver, WA, found that zirconium was superior to graphite and used zirconium equipment to produce up to 90%  $\text{H}_2\text{O}_2$ . The average maintenance-free life of the heat exchanger was 10 years; graphite exchangers failed after 12–18 months of service. The graphite equipment failure was attributed to the leaching of the binder from the graphite by the 35%  $\text{H}_2\text{SO}_4$  feed, which created a porous condition and ultimately caused failure.

The experience of zirconium in peroxide production led to the replacement of the graphite heat exchangers with zirconium shell and tube exchangers in the manufacturing of acrylic films and fibers. In this application, the  $\text{H}_2\text{SO}_4$  concentration was as high as 60% at 150 °C. Another major application in  $\text{H}_2\text{SO}_4$  concerns the manufacture of methyl methacrylate. The system at Rohm and Haas' plant in Deer Park, Texas, includes pressure vessels, columns, heat exchangers, piping systems, pumps, and valves all made from zirconium. A zirconium unit, which was built more than 20 years ago, is still in service.

Zirconium is also widely used for column internals and reboilers in the manufacture of butyl alcohol. The operating conditions are 60–65%  $\text{H}_2\text{SO}_4$  at

temperatures to boiling and slightly above. Zirconium may corrode under upset conditions of elevated concentrations and when such impurities as  $\text{Fe}^{3+}$  are present. Zirconium has been used in  $\text{H}_2\text{SO}_4$  recovery and in recycle systems in which fluorides are not present, and the acid concentration does not exceed 65%. A major application for zirconium is in iron and steel pickling, using hot 5–40%  $\text{H}_2\text{SO}_4$ .

Rayon is a manmade textile fiber, and most of today's rayon is made by the viscose process. Equipment made of graphite was popular for use in the  $\text{H}_2\text{SO}_4$ -affected areas of this process, yet is vulnerable to breakdowns. Avtex Fiber, Inc. began experimenting with zirconium equipment in 1970. Zirconium's excellent performance prompted Avtex to convert more pieces of equipment to zirconium, which included 10 acid evaporators, 14 shell- and tube heat exchangers, and 12 bayonet heat exchangers. In addition to dramatically reducing maintenance costs and downtime, the zirconium equipment improved operating efficiency and lowered overall energy costs.

Hydroxyacetic acid (HAA), also known as glycolic acid, can be produced in a synthetic process other than being extracted from natural sources. Under high pressure (30–90 MPa) and temperature (160–200 °C), formaldehyde reacts with carbon monoxide and water in the presence of an acidic catalyst, such as sulfuric acid, to form HAA. Dupont could not rely on a silver lining for reliable service in this process as silver showed poor erosion resistance in the piping system. There were cases of blowouts in the piping due to failure of the lining. By the mid-1980s, zirconium lining was evaluated when other materials, such as glass, ceramic, stainless alloys, and titanium were found unsuitable. Zirconium is well known for its corrosion resistance in weak sulfuric acid at temperatures up to and above 260 °C. An 8-month field test at Dupont indicated that a zirconium tube would not corrode in the most severe service section of the process. Zirconium's excellent resistance to erosion is also apparent and consequently, Dupont replaced silver lining with zirconium lining in piping sections more than 5 years ago. It was estimated that zirconium lining would last at least three times as long as silver lining.

#### 3.14.6.2 Processes Using Halogen Acids

Zirconium has many applications in HCl, such as the production of concentrated HCl and polymers. Zirconium heat exchangers, pumps, and agitators have been used for more than 15 years in an azo dye

coupling reaction. In addition to being very corrosion resistant in this medium, zirconium does not plate out undesirable salts that would change the color and stability of the dyes.

Lactic acid is commercially produced either by fermentation or by synthesis. The synthetic process is based on lactonitrile, which is prepared by reacting acetaldehyde with hydrogen cyanide at up to 200 °C. Lactonitrile is then hydrolyzed in the presence of HCl to yield lactic acid. In the HCl-affected areas, suitable materials are limited. Glass-lined materials are prone to breakdowns. Stainless alloys corrode and introduce toxic materials to the process stream. Titanium and its alloys are susceptible to crevice corrosion in hot chloride solutions. Zirconium is ideal for this process. Since lactic acid is produced as a fine chemical, contamination has to be prevented in all areas. Oxidizing HCl conditions resulting from the presence of ferric or cupric ions are avoided. Moreover, zirconium is highly resistant to crevice corrosion in chloride solutions. Since the 1970s, zirconium equipment has provided excellent service in lactic acid production.

Other applications in HCl include the breaking down of cellulose in the food industry and the polymerization of ethylene chloride, which is carried out in HCl and chlorinated solvents.

Zirconium and its alloys have been identified to offer the best prospects from a cost standpoint as materials for an HI decomposer in hydrogen production. They resist attack by HI media (gas or liquid) from room temperature to 300 °C. Most stainless alloys have adequate corrosion resistance to HI only at low temperatures.

### 3.14.6.3 Processes Using Nitric Acid

There is an increasing interest in the use of zirconium for HNO<sub>3</sub> service. For example, because of the high degree of concern over safety, zirconium is chosen as the major structural material for the critical equipment used to reprocess spent nuclear fuels.

In most HNO<sub>3</sub> service, stainless steel has been the workhorse for decades. The excellent compatibility between zirconium and HNO<sub>3</sub> was not thought to be needed. This situation changed when nitric acid producers started to modernize their technology in the late 1970s. Conventionally, HNO<sub>3</sub> is manufactured by oxidation of ammonia with air over platinum catalysts. The resulting nitric oxide is further oxidized into nitrogen dioxide and then absorbed in water to form HNO<sub>3</sub>. Acid of up to 65% concentration is

produced by this process. Higher concentration acid is produced by distilling the dilute acid with a dehydrating agent. Before the 1970s, dual-pressure processes were the dominant means of HNO<sub>3</sub> production. A typical dual-pressure process operates the converter at about 500 kPa and the absorber at about 1100 kPa. In the late 1970s, Weatherly, Inc. introduced a high mono-pressure process which operates at 1300–1500 kPa. The advantages of this new process include:

- greater productivity due to higher operating pressure;
- smaller equipment resulting in a lower capital cost;
- higher energy recovery capabilities.

The new process was first tried in 1979 when Mississippi Chemical in Yazoo City, MS, retrofit their existing plant with a new compressor system to increase pressure for greater productivity and energy efficiency. It was at this point that severe corrosion problems were discovered. Prior to the upgrade, the cooler condenser was constructed of type 304L stainless steel tubesheets and type 329 stainless steel tubes. Under the previous operating conditions, the cooler condenser had experienced some corrosion, which was managed by plugging tubes and replacing the unit every 3 to 4 years. Shortly after the upgrade, with an operating temperature and pressure of 200 °C and 1035 kPa, 10% of the type 329 stainless steel tubes were found to be leaking. This condenser was replaced with a unit using type 310L stainless steel, which had to be replaced after 13 months of operation. The original condenser with new tubes of improved grade 329 stainless steel was replaced by the 310L unit. Mississippi Chemical began looking for alternatives.

In an attempt to find a solution to this problem, autoclave tests were conducted on many newer types of stainless steels and zirconium in solutions up to 204 °C and at concentrations up to 65%. Clearly, zirconium was the only suitable material for the mono-pressure process. Corrosion rates of zirconium coupons were consistently below 25 μm year<sup>-1</sup>. The next step was to test zirconium tubes in service. Several tubes were installed into a rebuilt stainless steel condenser. They were destructively examined after 13 months and showed no signs of corrosion. Zirconium tubes were then placed in another condenser for 1 year. Once again, there were no signs of corrosion.

Consequently, Mississippi Chemical replaced its stainless steel cooler condenser with one constructed

from zirconium tubes and zirconium/304L stainless steel explosion-bonded tubesheets. This unit contains more than 18 km of zirconium tubing. In service since 1984, the zirconium unit has already outperformed the stainless steel predecessors. Thereafter, several zirconium cooler condensers have been built for other  $\text{HNO}_3$  producers.

Mono-pressure plants are not the only ones to use zirconium as a solution to corrosion problems. Certain plants use a distillation process to increase the acid concentration. The acid is passed through a reboiler and enters a distillation column to drive off water for concentrating the acid. In 1982, Union Chemicals replaced the bottom portion of each of two distillation columns and the tube bundles of each of two reboilers. The lower parts of the columns had been constructed originally with type 304L stainless steel that experienced corrosion problems. Titanium was tried, but also failed. While glass-lined steel did not have the corrosion problems experienced by type 304L stainless steel and titanium, the maintenance costs were found to be unacceptable. Zirconium provides significantly improved corrosion resistance without adding maintenance costs. Zirconium also solved corrosion problems in the reboilers. Prior to the installation of zirconium tube bundles, both 304L and titanium tube bundles had failed in less than 18 months of operation.

With proper design and fabrication, zirconium's susceptibility to SCC can be suppressed in highly concentrated  $\text{HNO}_3$ . For example, an Israeli chemical plant uses zirconium tubes in a U-tube cooler that processes bleached  $\text{HNO}_3$  at concentrations between 98.5 and 99%. The unit cools the acid from 70–75°C to 35–40°C. Previously, U-tube coolers were made from aluminum, which failed in 2–12 weeks. The zirconium unit has been in service for more than 2 years, operating 24 h a day, 6 days a week.

### 3.14.7 Safety

Zirconium is low in toxicity and is not known to be a carcinogen. The permissible exposure limit for zirconium set by various health agencies is  $5 \text{ mg m}^{-3}$ . For comparison, the limit for iron is  $1 \text{ mg m}^{-3}$ . One major concern is zirconium's reactivity. Under most conditions, the reactivity works toward zirconium's advantage. This reactivity allows zirconium to react spontaneously with oxygen to form a protective film, which suppresses its reactivity. Consequently, zirconium can be safely used under most conditions.

Nevertheless, unsafe situations may develop when this reactive nature is overlooked.

Heat of formation for zirconium dioxide at 25 °C is  $1101.3 \text{ kJ mol}^{-1}$ . It is potently exothermic. The generated heat can be easily absorbed by a large piece of zirconium. After the oxide film is formed, the oxidation rate will decrease quickly and pose no problems. However, when the heat is generated at a very small area, ignition may occur. Care should be exercised in handling fine materials including powder, sponge, machine chips, and thin foils. Ignition of fine materials will result in a very rapid, high temperature fire, which can be extinguished by using dry salt or sand. Attempts to extinguish a large zirconium fire with water will only result in scavenging of the oxygen atoms in the water molecules by the burning zirconium, leaving the hydrogen molecules to act as additional fuel or explosion source. These very large fires should be allowed to burn out by themselves.

It is normally safe to handle a large piece of zirconium. Still, ignition may occur when this piece experiences an enhanced oxidation reaction in a confined space. Under this condition, generated heat cannot easily dissipate, leading to escalated oxidation reaction and ignition becomes possible.

Furthermore, when zirconium's corrosion resistance is grossly exceeded in certain environments, pyrophoric films may form on its surface.<sup>48</sup> These environments include concentrated sulfuric acid and ferric chloride-containing solutions that may induce massive localized corrosion. Consequently, the solid surface is broken down into tiny pieces that contain corrosion products and unreacted zirconium particles. When unreacted particles are fine enough, ignition may occur. This pyrophoricity can be neutralized by treating it with steam.<sup>48</sup> Unreacted particles will oxidize in steam to become stable oxide or cover with a thick layer of oxide film. Treating time is about 20 min when the steam temperature is 250 °C. A longer time is needed when a lower temperature steam is used.

### 3.14.8 Future Possibilities

Trends in the CPI may offer some clues for zirconium's applications in coming years. They include improving product quality, developing new technologies, and assuring safety and environmental protection.

In compatible environments, zirconium yields few zirconium ions, which are colorless and

biocompatible. Zirconium becomes attractive for producers who do not just want to make a product, but want to make a product of high quality without undesirable impurities. The presence of undesirable impurities may affect the product's performance or may be harmful to the environment. The use of zirconium in the urea production is an example. Another example is the use of zirconium in the production of phenolic resins.<sup>75</sup> Purely from the viewpoint of mechanical integrity, iron-based alloys are suitable structural materials. However, in order to make phenolic resins for high-end uses, the products need to be colorless and very low in impurities. Then, zirconium becomes the necessary choice. If this trend continues, zirconium should find more applications in the food, the electronic, and the pharmaceutical industries.

There is the increasing demand for energy and the effort in reducing greenhouse gases. Many technologies are being developed to produce renewable energy. As indicated in the section of halide-containing processes, zirconium looks promising for the production of hydrogen from the decomposition of HI. In certain ethanol processes, the hydrolysis of starch into glucose is accomplished rapidly by treatment with dilute sulfuric acid at elevated temperature. High performance alloys like zirconium are needed for this type of processes.

Moreover, safer, advanced nuclear reactors have been developed. There is a renewed interest in nuclear energy. Many new nuclear power plants are being built and planned. Demand for zirconium in this arena will certainly rise and with it demand for optimized alloys that permit longer service and, consequently, higher utilization of the available uranium fuel.

Finally, developments in nanotechnology create new materials and corrosion challenges. Certain nanodevices process small amounts of corrosives through relatively large areas of corroding surfaces. Alloys of low corrosion rates may be unsuitable as structural materials. Zirconium could be a good match for certain nanodevices.

### 3.18.1 Metallurgy

Beryllium is a light metal ( $1.85 \text{ g cm}^{-3}$ ) with a hexagonal close-packed structure (axial ratio 1.568). [Table 1](#) displays the composition of S200D Be versus S200F two common grades of Be (Brush Wellman), both of which are fabricated from powder materials. The main difference between these grades of Be is the concentrations of BeO, iron, and aluminum (Al). Both grades are manufactured by comminuting vacuum cast ingots, followed by grinding or milling to produce powder.<sup>1</sup> In this process, a thin oxide layer forms around the Be powder particles, resulting in a high BeO content and resultant BeO inclusions that form after hot isostatic pressing. The grain sizes of these two grades of Be are on the order of 10–40  $\mu\text{m}$ , which is characteristic of powder products as the BeO particles pin grain boundaries and retard grain growth.

The most notable of its mechanical properties is its low ductility at room temperature. Deformation at room temperature is restricted to slip on the basal plane, which takes place only to a very limited extent. Consequently, at room temperature, beryllium is, by normal standards, a brittle metal, exhibiting only ~2–4% tensile elongation. Mechanical deformation increases this by the development of preferred orientation, but only in the direction of working and at the expense of ductility in other directions. Ductility also increases very markedly at temperatures

above ~300 °C with alternative slip on the (1010) prismatic planes. In consequence, all mechanical working of beryllium is carried out at elevated temperatures. It has not yet been resolved whether the brittleness of beryllium is intrinsic or results from its impurities. Solid solubility of other metals in Be is very low and, to date, it has not been possible to overcome the brittleness problem by alloying.

### 3.18.2 Extraction and Fabrication

Beryllium is extracted from the main source mineral, the aluminosilicate beryl, by conversion to the hydroxide and then through either the fluoride or the chloride to the final metal. If the fluoride is used, it is reduced to beryllium in magnesium by a Kroll-type reaction. The raw metal takes the form of ‘pebble’ and contains much residual halides and magnesium. With the chloride, on the other hand, the pure metal is extracted by electrolysis of a mixture of fused beryllium chloride and sodium chloride. The raw beryllium that results is dendritic in character and contains residual chloride.

Before further processing, the raw metal must be purified. Various methods of leaching have been tried on a laboratory scale, but in practice, the method usually adopted is vacuum induction melting. The ingot so produced is then converted to powder by reducing it to chips/turnings, followed by grinding.

**Table 1** Typical Be S200D and Be S200F chemistries

Constituents	S200F	S200D
Beryllium	≈98.5	≈98.0
Beryllium oxide (BeO)	≤1.5	≤2.0
Aluminum	0.10	0.16
Carbon	0.15	0.15
Iron	0.13	0.18
Magnesium	0.08	0.08
Silicon	0.06	0.08
Other metallic impurities	0.04	0.04

All values are given in weight percent.

On a laboratory scale, the grinding is generally done by ball milling; while in production, milling is carried out between beryllium-faced plates.

The particle size of powder most often used for consolidation is 200 mesh (74 μm sieve aperture), and the most widely practiced method of consolidation is hot pressing *in vacuo*.

Setting aside the necessity for hot working and the toxicity issue, the fabrication of consolidated beryllium generally follows normal lines; rolling, extrusion, drawing, forging, etc. have all been successfully carried out. It is interesting to note that because of the high chemical activity of beryllium, allied to the method of consolidation from powder, the usual grade of metal contains ~1–2% of beryllium oxide as described earlier. It could therefore, be considered almost a mild cermet rather than a conventional pure metal. Specifications for typical chemical composition are detailed in [Table 1](#).

### 3.18.3 Aqueous Corrosion Behavior

#### 3.18.3.1 Commercial Grades of Be

The initial studies of the breakdown of passivity in beryllium focused on those environments expected to be generated in the early ‘development reactors’ where beryllium was used as a neutron reflector, and are not available in the general literature.<sup>2</sup> In these studies, beryllium was exposed to various concentrations of hydrogen peroxide (a water radiolysis product) as a function of solution pH and temperature. At the end of exposure periods, coupons were evaluated for pit density and penetration depth. The effect of coupling beryllium to aluminum and stainless steels on corrosion rate was also investigated. Although beryllium corrosion rates were high in some of the simulated environments, service lifetimes of beryllium reflectors exposed to high-purity,

low-temperature, irradiated water were reported to be good.<sup>3</sup>

At this point, it is worth noting that the Be ion exists only in the Be(II) oxidation state; however, early literature, sometimes incorrectly, reported a Be(I) oxidation state.<sup>4</sup> These reports were later discredited. Sheth used weight loss to study the anodic dissolution of Be in numerous solution, including halides (F<sup>−</sup>, Cl<sup>−</sup>, . . .), sulfates, and phosphates.<sup>5</sup> Thus, reports of the existence of a Be(I) oxidation state can be explained by Sheth’s observation of metal disintegration, unoxidized loss of metal that skewed correlations between charge passed and weight loss data.

In general, early literature on other forms of beryllium corrosion is limited. Although some polarization studies of beryllium in chloride and sulfate environments have been conducted,<sup>6</sup> other investigations focused on weight loss<sup>7</sup> and visual observation<sup>3,8</sup> to evaluate susceptibility to corrosion. Levy found that beryllium is susceptible to pitting attack in chloride at its open circuit potential (OCP) and uniform attack (i.e., ‘. . . a thick, dark anodic film. . .’) in NaNO<sub>3</sub> solution.<sup>6</sup> Similar observations were made by Prochko.<sup>8</sup> Additional studies by Stonehouse and Beaver used humidity cabinet experiments to evaluate the susceptibility of beryllium to corrosion from surface residue deposited during machining.<sup>3</sup>

Other investigations have focused on the corrosion associated with beryllium carbides. One of the primary impurities in historic grades of beryllium is carbon, 0.2 wt% or more, which results in the formation of second-phase particles (Be<sub>2</sub>C). In the presence of water, these carbides react quickly to form BeO ( $\Delta G = -581 \text{ kJ mol}^{-1}$ )

as discussed by Mueller.<sup>9</sup> It may be noted, however, that the relative surface concentration of carbides is low and once the carbide has been consumed by this reaction with water, no further role of carbides is expected.

Gulbrandsen *et al.* studied the passivity of Be in phosphoric acid, oxalic acid, phosphate, borate, carbonate buffer solutions, and sodium hydroxide to characterize the passive current density over a pH of 1–15.<sup>10</sup> It was shown that a minimum in passive current density for beryllium occurs near pH 11 and increases logarithmically in more acidic and alkaline solutions. Moreover, it was also observed for any one solution pH that the passive current density is a function of ionic strength. However, Gulbrandsen did not address the formation of soluble oxalic and phosphoric beryllium complexes that form in some of

the solutions used. This may account for their observation of steady-state passive currents below the thermodynamic limit of pH 2.

More recently, Hill *et al.* studied the passivity and break down of 98.5% pure Be.<sup>11</sup> The solutions used were sulfuric acid adjusted to a solution pH of 1 and 2, 0.25 M boric acid (pH=4.6), 0.05 M sodium borate/0.5 M boric acid (pH=7.2), 0.025 M sodium borate/0.05 M sodium hydroxide (pH=10.7), and sodium hydroxide adjusted to a solution pH of 12.5. A summary of the corrosion current densities and passive current densities as a function of pH is presented in Figure 1. Below pH 2, Be exhibited active dissolution at all applied anodic potentials. In solution pH 2–12.5, it was shown that Be exhibits passive anodic behavior at potentials between the OCP and 0.6 V versus saturated calomel electrode (SCE). Anodic polarization above 0.6 V SCE in the pH range of 2–12.5 led to an abrupt increase in the passive current density, followed by oxygen evolution. This abrupt increase was attributed to a change in the specific resistivity of the passive film, as determined by electrochemical impedance spectroscopy (EIS). EIS experiments were also used to show that the oxide growth rate on Be is  $6.4 \text{ \AA V}^{-1}$  over the potential range of 0–4 V. At higher anodization potentials, the growth rate appeared to be somewhat lower likely due to an increase in oxide conductivity.

Breakdown of passivity was studied in chloride and fluoride solutions. In chloride, the attack was found to be localized. Typical potentiodynamic polarization curves for S200D beryllium in deaerated

**Figure 1** Passive current density,  $i_{\text{pass}}$ , and corrosion current density,  $i_{\text{corr}}$ , as a function of solution pH. A minimum in  $i_{\text{pass}}$  and  $i_{\text{corr}}$  exists between a pH of 4.5 and 10.7. Reproduced from Hill, M. A.; Butt, D. P.; Lillard, R. S. *J. Electrochem. Soc.* **1998**, 145, 2799, with permission from The Electrochemical Society.

NaCl solutions ranging in concentration from  $10^{-4}$  to 1 M  $\text{Cl}^-$  are presented in Figure 2. For  $\text{Cl}^-$  concentrations below 1 M, the anodic polarization of the sample was characterized by a region of passivity followed by a logarithmic increase in the current density, which corresponded to the onset of pitting corrosion. In deaerated 1 M  $\text{Cl}^-$ , pitting at the OCP was observed. The voltage that corresponded to the onset of pitting corrosion,  $E_{\text{pit}}$ , was found to decrease logarithmically with increasing chloride concentration according to the relationship

$$E_{\text{pit}} = -0.067 \log[\text{Cl}^-] - 1.01 \quad [2]$$

where  $E_{\text{pit}}$  is in volts versus SCE and  $[\text{Cl}^-]$  is the concentration of chloride in molarity (Figure 3). As seen in this relationship, a  $-0.067 \text{ V}$  change in the pitting potential per decade of chloride concentration was observed. A similar relationship between  $E_{\text{pit}}$  and chloride concentration has been noted for pure aluminum (Al); however, the relationship between the pitting potential of Al in  $\text{Cl}^-$  concentration is  $-0.091 \text{ V}$  per decade  $[\text{Cl}^-]$ . For 18Cr–8Ni stainless steel, the pitting potential has been found to vary by  $-0.088 \text{ V}$  per decade  $[\text{Cl}^-]$ . Thus, the pitting potentials of Al and stainless steel are more sensitive to changes in chloride concentration than are those of Be. In addition, as defined by the  $y$ -intercept in eqn. [1], for any one chloride concentration,  $E_{\text{pit}}$  for Be is more negative than those of Al and stainless steel.

Hill *et al.* also investigated the breakdown of passivity in sodium fluoride (NaF) solutions ranging in concentration from  $10^{-1}$  to  $10^{-4} \text{ M F}^-$ . At a

**Figure 2** Beryllium polarization curves as a function of chloride concentration showing a decrease in pitting potential with an increase in chloride concentration. Reproduced from Hill, M. A.; Butt, D. P.; Lillard, R. S. *J. Electrochem. Soc.* **1998**, 145, 2799, with permission from The Electrochemical Society.

$F^-$  concentration of  $10^{-4}$  M, the anodic polarization of the sample was characterized by a region of passivity followed by a logarithmic increase in the current density which corresponded to the onset of pitting corrosion. The pitting potential was found to be  $-0.742$  V SCE. In comparison, for  $10^{-4}$  M  $Cl^-$ , the pitting potential was  $-0.773$  V SCE. Pitting type corrosion was also observed for  $10^{-3}$  M  $F^-$ ; however, no region of passivity was observed upon anodic polarization. While at the lower fluoride concentrations the breakdown of passivity was localized, at the higher fluoride concentrations ( $10^{-1}$  to  $10^{-2}$  M) beryllium was susceptible to uniform attack.

### 3.18.3.2 High-Purity Be

Lillard investigated the factors influencing the transition from metastable to stable pitting high-purity single crystal beryllium.<sup>12</sup> The goal of that work was to determine the relationship between physical bulk

**Figure 3** Pitting potential as a function of chloride concentration displaying a logarithmic relationship between  $E_{pit}$  and  $[Cl^-]$ . Reproduced from Hill, M. A.; Butt, D. P.; Lillard, R. S. J. *Electrochem. Soc.* **1998**, 145, 2799, with permission from The Electrochemical Society.

metal properties, such as crystallographic orientation of the surface, and the critical pitting environments in terms of ohmic and mass transport models on the breakdown of passivity. To accomplish this, electrodes were fabricated from one zone-refined Be single crystal (99.99% Be via ion coupled plasma (ICP) analysis) that was sectioned using electrical discharge machining (EDM). Experiments were conducted on the following surfaces: (0001) the basal plane, (10–10) a Type-I prism plane, and (11–20) a Type-II prism plane. The solutions used in this study were sulfuric acid adjusted to a pH of 2 and near-neutral 0.01 M sodium chloride.

A summary of the critical parameters from the potentiodynamic polarization data for the three orientations investigated is presented in [Table 2](#).  $E_{pit}$  was found to decrease with electrode orientation in the order (0001) > (10–10) > (11–20). The scatter in  $E_{pit}$  for each orientation was moderate, and in only one case did the potential regions overlap; the maximum  $E_{pit}$  for the (11–20) surface was 0.01 V greater than the minimum  $E_{pit}$  for the (10–10) surface. Post-exposure observation found that the corrosion pits were not hemispherical, rather, they were highly crystallographic in nature ([Figure 4](#)). Corrosion pits on the surfaces of prism planes (10–10) and (11–20) were characterized by interiors that had crystallographically oriented, parallel plates of unattacked material. In comparison, the morphology of the corrosion pits in polycrystalline Be are also characterized by parallel plates of unattacked Be, separated by trenches of similar size and shape ([Figure 5](#)). Similar morphologies were also observed by Straumanis in polycrystalline Be.<sup>13</sup> The orientation dependence of pit propagation in single crystal and polycrystalline Be was explained within the context of the metal–metal bond strength as a function of surface orientation.<sup>14</sup> Using the calculations of the electron density distribution, it was proposed that crystallographic pits propagate preferentially at ledges/steps that

**Table 2** Critical parameters from potentiodynamic polarization curves for Be single crystals in 0.01 M NaCl as a function of surface orientation

Surface orientation	$E_{corr}$ (V vs SCE)	$i_{pass}$ ( $A\ cm^{-2}$ )	$E_{pit}$ (V vs SCE)
S200D polycrystalline	$-1.15, \sigma = 0.03$	$6.1 \times 10^{-7}, \sigma = 0.4 \times 10^{-7}$	$-0.862, \sigma = 0.030$
(0001)	$-1.28, \sigma = 0.20$	$1.1 \times 10^{-7}, \sigma = 0.16 \times 10^{-7}$	$-0.644, \sigma = 0.035$
(10–10)	$-1.39, \sigma = 0.12$	$1.8 \times 10^{-7}, \sigma = 0.23 \times 10^{-7}$	$-0.732, \sigma = 0.027$
(11–20)	$-1.28, \sigma = 0.08$	$1.3 \times 10^{-7}, \sigma = 0.34 \times 10^{-7}$	$-0.800, \sigma = 0.047$

The data from polycrystalline S200D grade Be (98.5% Be) from Stonehouse is also presented.

**Figure 4** SEM micrograph of typical corrosion pits in the (11-20) surface of Be after potentiodynamic polarization above the pitting potential in 0.01 M NaCl. Orientation of the lamella (and pit walls) was parallel to the [0001] direction and normal to the (11-20) surface. Reproduced from Lillard, R. S. *J. Electrochem. Soc.* **2001**, 148, B1, with permission from The Electrochemical Society.

**Figure 5** SEM micrograph of corrosion pits in S200D grade (powder pressed) Be showing orientation of pit walls and parallel plates of unattacked Be lamella (normal to arrows) left behind after pit propagation. The size of any one set of parallel plates is consistent with the grain size of this material ( $\sim 10$ – $40 \mu\text{m}$ ). Reproduced from Lillard, R. S. *J. Electrochem. Soc.* **2001**, 148, B1, with permission from The Electrochemical Society.

expose susceptible lattice positions by removing atoms of lowest bond strength.

At potentials more positive than the repassivation potential,  $E_{\text{rp}}$ , a unique type of current transient was observed in the current/time data collected during potentiostatic experiments. This type of transient

(a)

(b)

**Figure 6** (a) A summary of the damage events; charge passed per event versus applied anodic potential (vs  $E_{\text{pit}}$ ) for the (0001) and the (10-10) surfaces in 0.01 M NaCl solution. (b) A summary of the damage events; total charge passed during all damage events versus applied anodic potential (vs  $E_{\text{pit}}$ ) for the same surfaces in shown in (a). Only damage events that repassivated were considered in these plots. Reproduced from Lillard, R. S. *J. Electrochem. Soc.* **2001**, 148, B1, with permission from The Electrochemical Society.

was always associated with a large amount of charge passed and visible damage on the electrode surface. The average charge passed, peak charge passed, and total number for damage transients increased with increasing anodic potential for each surface orientation are shown in [Figure 6](#). From these results, it was concluded that the transition from metastable to stable pitting is governed by surface damage, and more likely, a bulk property of the metal such as surface energy/metal bond strength.

### 3.18.3.3 Galvanic Effects – The Influence of Be Inclusions

As discussed in Sections 3.18.1 and 3.18.2, commercially available beryllium is generally a powder-processed material. In addition to the relatively high BeO content, most impurity concentrations in commercial beryllium exceed the solubility limit and produce precipitates. The precipitates that form generally are present as both binary and ternary intermetallic phases with Be. Of the possible intermetallics that may form in the commercial grades of Be,  $\text{FeBe}_5$ ,  $\text{TiBe}_{11}$ , and  $\text{FeAlBe}_4$  have been observed on fracture surfaces,<sup>15</sup> although the galvanic relationships between these precipitates and the Be matrix were not defined. These galvanic relationships impact on environmental fracture models from the standpoint of crack tip chemistry and potential, as well as localized corrosion models, from either a cathodic reduction or anodic site chemistry standpoint. In addition, they play an important role in the localized corrosion of Be.<sup>11,16</sup>

To enhance the understanding of the mechanisms of localized corrosion and stress corrosion cracking in commercial grades of beryllium, Hill *et al.* initiated a study of the galvanic relationships between Be and the single phase particles.<sup>17</sup> The beryllides studied were  $\text{TiBe}_{12}$ ,  $\text{FeAlBe}_4$ , and  $\delta$ -phase iron beryllide  $\text{FeBe}_5$  (nominal composition  $\text{FeBe}_{12}$ , crystallographically  $\text{FeBe}_5$ ). They were prepared by arc-melting and casting high-purity elemental material. The solutions studied were of sulfuric acid adjusted to a pH of 2, 0.05 M sodium borate/0.5 M boric acid (pH=7.2), 0.025 M sodium borate, and sodium hydroxide adjusted to a pH of 10.5 and sodium hydroxide adjusted to a solution pH of 12.5.

In a pH range of 7.2–12.5, all of the beryllides exhibited passive behavior. Most notably, a transpassive region was noted in the Fe-containing beryllides at a solution pH of 7.2. With respect to the pH 2 solution, active dissolution of all beryllides was observed at this pH. This was confirmed by post-exposure examinations of the samples, which revealed a large quantity of damage.

A summary plot of OCP values for each beryllide along with that of commercially pure Be is shown in Figure 7 as a function of pH. These data were collected after 48 h of immersion and represent steady-state OCP values. This plot is useful in that it allows one to determine the galvanic relationships between second phase particles in a Be matrix. For example, with respect to  $\text{FeAlBe}_4$ , the OCP is

**Figure 7** A summary plot of OCP for  $\text{FeBe}_5$ ,  $\text{FeAlBe}_4$ , and  $\text{TiBe}_{12}$  as a function of solution pH. Data were collected after 48 h of immersion and represent steady-state OCP values. Reproduced from Hill, M. A.; Hanrahan, R. J.; Haertling, C. L.; Schulze, R. K.; Lillard, R. S. *Corrosion* **2003**, 59, 424, with permission from NACE International.

more negative than that of beryllium in the pH range of 2.0–10.5. Thus, from a mixed potential standpoint, when coupled in commercial Be under these conditions, the  $\text{FeAlBe}_4$  may act as a site for active dissolution. This finding was confirmed experimentally in galvanic couple tests.

### 3.18.3.4 Environmental Fracture

Reports on environmental fracture of Be are limited. The first reported work on the stress-corrosion cracking of beryllium related to its use in water containing 0.005 M hydrogen peroxide at pH 6–6.5 and at  $\sim 90^\circ\text{C}$ .<sup>18</sup> Although some pitting occurred in these exposure, there was no evidence of stress corrosion, even though the tests employed extruded metal stressed at up to 90% of the yield stress. Later work included stress corrosion studies of Be tensile bars' exposure to synthetic seawater.<sup>19</sup> In that environment, time to failure decreased from  $\sim 2350$  h at an applied stress of 1220 psi to 40 h at an applied stress of 40000 psi. Further, crack initiation appeared to be related to localized corrosion of the sample. Electron microscopy of the fracture surfaces found the crack habit to be transgranular in character. Subsequent work by the same group studied the influence of applied current, anodic and cathodic, on time to failure.<sup>20</sup> As might be anticipated, applied anodic currents promoted pitting attack and decreased time to failure. However, applied cathodic currents reduced pitting attack and eliminated environmental fracture altogether.

### 3.18.3.5 Corrosion Control

From what has already been indicated, it will be apparent that the use of beryllium in most commercial environments involving moisture will require some form of surface protection to mitigate pitting corrosion. Corrosion control measures range from painting<sup>21</sup> to Zn galvanizing.<sup>22</sup> In addition to those studies, Paine and Stonehouse<sup>23</sup> used a high temperature silicone-based paint on beryllium heat-sinks for aircraft brakes. They also studied cathodic protection in fresh- and saltwater solutions via manganese plating on the steel parts that were mated to Be. Other work on cathodic protection includes the stress corrosion study in aerated synthetic seawater described in [Section 3.18.3.4](#). There, an impressed cathodic potential was used to protect Be from localized attack by chlorides.<sup>20</sup>

Booker examined the application of chromate conversion coatings (CCCs) to mitigate Be corrosion in chloride environments.<sup>24</sup> As the coating bath composition was not specified in that paper, one can only presume that these coatings were based on Alodine® (a nitric acid-based solution containing NaF/KBF<sub>4</sub>/K<sub>2</sub>ZrF<sub>6</sub>/K<sub>3</sub>Fe(CN)<sub>6</sub>). Chromium deposition (and ultimately corrosion protection) was greatly dependent on the manner in which the sample was cleaned and etched. To obtain the best performance, it was necessary to etch the samples in a nitric acid–hydrofluoric acid solution just prior to coating. The need for this F<sup>−</sup> base etch has been confirmed in our laboratory. Samples prepared in this manner were described by Booker as having satisfactory performance in high humidity and salt spray exposures. A similar investigation of CCCs was reported by Levy.<sup>6</sup>

The use of anodization to control Be corrosion has been somewhat problematic. Kerr reported on the anodization of Be in an aqueous solution of 10% nitric acid containing 200 g l<sup>−1</sup> CrO<sub>3</sub> (chromic acid).<sup>25</sup> In that work, samples were anodized at a constant current density of 0.03 A cm<sup>−2</sup>. Although films as thick as 0.35 mm were grown in this solution, when the limiting voltage was reached, the current remained constant with time. Thus, it was concluded that for Be, there is no voltage-dependent limiting oxide thickness as is the case for other valve metals such as aluminum, zirconium, and tantalum. In an attempt to overcome this difficulty, Kerr explored the use of an ammoniacal glycol solution (25 g l<sup>−1</sup> NH<sub>3</sub> in ethylene glycol), which has been used successfully

to grow compact insulating films on aluminum. For current densities of 1.9 mA cm<sup>−2</sup>, limiting thicknesses were formed on Be. However, as was the case in chromic acid, the current remained roughly constant with time and it was concluded that the films formed in this solution were not insulating. Subsequently, Hill has shown that the specific resistivity of the oxide on Be decreases with increasing applied potential and undergoes a transition at ~2 V versus NHE.<sup>11</sup> This was attributed to a change from a compact to a more porous film though this behavior may owe to other factors such as the incorporation of unoxidized metal into the film. Levine has also reported on anodic films grown in ammoniacal glycol solution and nitric acid solutions containing chromic acid.<sup>26</sup> Similarly, films grown in nitric acid were always crystalline, while those grown in ethylene glycol were amorphous. Levine reported current potential relationships similar to Kerr, indicating that these films were not insulating. Shetata has reportedly been able to overcome this problem by growing films on Be in near-neutral ethylene glycol saturate with sodium phosphate dibasic and sodium sulfate.<sup>27</sup> For constant current densities in the order of 2–3 mA cm<sup>−2</sup>, samples anodized in this solution quickly reached limiting voltages of 50 V (<30 s) and, correspondingly, decreasing current density with time. Films grown on Be in this manner were insulating and are of the order of 5 μm thick. Unfortunately, we have not been able to reproduce these results in our own laboratory.

## 3.18.4 High Temperature Oxidation of Be and the Beryllides

### 3.18.4.1 Beryllium

Early high temperature oxidation studies of Be focused on dry and moist oxygen environments. Gulbransen examined the reaction of Be (Brush) with dry oxygen (0.76–7.6 cm O<sub>2</sub>) over the temperature range of 350–950 °C.<sup>28</sup> At lower temperatures (below 825 °C) and high O<sub>2</sub> pressures (7.6 cm O<sub>2</sub>), the oxidation rate appeared to fit a logarithmic or inverse logarithmic law, while at higher temperatures, the rates appeared to be parabolic ([Figure 8](#)). Weight gain data ( $W$ ) as a function of time ( $t$ ) were fit to a parabolic rate law,  $W^2 = Kt + C$ , where  $K$  is the parabolic rate constant. Below 650 °C,  $K$  increased from  $0.93 \times 10^{-16}$  cm<sup>2</sup> s<sup>−1</sup> at 350 °C to  $5.4 \times 10^{-15}$  cm<sup>2</sup> s<sup>−1</sup>; at 950 °C,  $K$  was equal to  $1.0 \times 10^{-12}$  cm<sup>2</sup> s<sup>−1</sup>.

**Figure 8** The influence of temperature on the oxidation rate of Be in dry O<sub>2</sub> at a pressure of 7.6 cm. Reproduced from Gulbransen, E. A.; Andrew, K. F. J. *Electrochem. Soc.* **1950**, 97, 383, with permission from The Electrochemical Society.<sup>28</sup>

Arrhenius plots of  $\log K$  versus  $1/T$  identified two activation energies for oxidation; below 750 °C, the activation energy was equal to 8.5 kcal mol<sup>-1</sup>, while above 750 °C, the activation energy was 50.5 kcal mol<sup>-1</sup> (Figure 9). Similar activation energies in the high temperature range were observed in the later work by Cubicciotti.<sup>29</sup> For Pechiney flake Be (referred to as 'French-flake' being produced in France), Be in 10-cm dry O<sub>2</sub> and temperatures below 650 °C, Alymore found higher oxidation rates and at temperatures greater than 650 °C with break-away oxidation observed.<sup>30</sup> Similar trends were found by Ervin, who concluded that the first stage of Be (Brush/NMC) oxidation is a protective diffusion controlled process (Be vacancies).<sup>31</sup> He further concluded that the formation of pits at accumulation sites of vacancies at the metal–oxide interface in this stage lead to a second, catastrophic stage of oxidation. To date, there is no clear explanation of discrepancy between the Gulbransen–Cubicciotti observations of passive behavior and low oxidation rates in the range of 350–950 °C and the works of Alymore–Ervin that found breakaway oxidation above 650 °C. For example, one investigator did not use powder product as compared with results from pressed disc or flake nor were there clear distinction between vendors (Brush versus Pechiney flake).

With respect to the addition of H<sub>2</sub>O, Alymore investigated oxidation rates for Be in moist O<sub>2</sub>

**Figure 9** Arrhenius plot from data in Figure 8 showing the parabolic rate constant as a function of inverse temperature ( $K$ ). Two unique behaviors, and thus activation energies, are observed above and below ~750 °C (1020 K,  $1/T = 0.00098$ ). Reproduced from Gulbransen, E. A.; Andrew, K. F. J. *Electrochem. Soc.* **1950**, 97, 383, with permission from The Electrochemical Society.

(10 cm O<sub>2</sub>, 1.2 cm H<sub>2</sub>O) and water vapor.<sup>32</sup> In 1.2-cm H<sub>2</sub>O and temperatures below 650 °C, oxidation rates were logarithmic/parabolic. After 300 h of exposure, the weight gains were of the order of 20 µg cm<sup>-2</sup>. Above 650 °C, breakaway oxidation was observed. In water vapor below 650 °C, rates were again logarithmic/parabolic and relatively low, less than 50 µg cm<sup>-2</sup>. Above 650 °C, breakaway oxidation was again observed.

The possible use of beryllium in nuclear engineering and in the aircraft industry encouraged considerable investigation into its oxidation characteristics in carbon dioxide and carbon monoxide (dry and moist) at temperatures of up to 1000 °C. For Pechiney-flake Be, Gregg found that the oxidation of Be in dry CO<sub>2</sub> (pressure of 10 cm) was logarithmic at temperatures equal to and below 550 °C and inverse logarithmic between 600 and 750 °C for exposure times up to 300 h (Figure 10).<sup>33</sup> They proposed that film thickening occurs via the outward diffusion of Be<sup>2+</sup> to react with chemisorbed carbon dioxide at the gas-oxide interface where the following reactions take place to form oxide and carbide species.

In moist CO<sub>2</sub> (total CO<sub>2</sub> pressure of 10 cm, with 1.2-cm partial pressure H<sub>2</sub>O) at temperature equal

to and below 650 °C, results were similar to those in dry CO<sub>2</sub>. However, at temperatures greater than 650 °C, breakaway oxidation was observed (Figure 11).<sup>34</sup> Radiotracer experiments in moist CO<sub>2</sub> found the build up of gas in the exposure vessel, which led the authors to conclude that water was reacting with the BeC to form methane:

Unfortunately, no conclusions concerning the mechanism of the breakaway oxidation were reported. Similar rate constants and threshold temperatures were found by Menzies for flake as well as Brush sheet and powder products in 300 psig CO<sub>2</sub>/300 ppm H<sub>2</sub>O for longer exposure periods (up to 8000 h).<sup>35</sup> Higgins investigated Be-CO<sub>2</sub>-H<sub>2</sub>O systems at higher temperatures and higher water content and found similar thresholds.<sup>36</sup> Raine and Robinson found that small additions of calcium greatly improved the resistance of Be to breakaway oxidation.<sup>37</sup> Further, it was found that the addition of Ca modified the pressure dependence of the corrosion reaction in CO<sub>2</sub>.

In dry carbon monoxide, Gregg found that the oxidation rates were greater by at least a factor of 10 than those observed in dry CO<sub>2</sub>; however, the transition temperatures from logarithmic to inverse logarithmic behavior that were reported in that study were similar to those reported by Gulbransen (Figure 8).<sup>38</sup> In this environment, the possible reactions are

**Figure 10** Oxidation of Be as a function of temperature in dry CO<sub>2</sub> at pressure of 10 cm. Reproduced from Gregg, S. J.; Hussey, R. J.; Jepson, W. B. *J. Nucl. Mater.* **1961**, 3, 175, with permission from Elsevier.<sup>33</sup>

**Figure 11** Oxidation of Be as a function of temperature in moist CO<sub>2</sub> at a total pressure of 10 cm with 1.2-cm partial pressure H<sub>2</sub>O. Reproduced from Gregg, S. J.; Hussey, R. J.; Jepson, W. B. *J. Nucl. Mater.* **1961**, 4, 46, with permission from Elsevier.

The higher oxidation rates observed in CO were attributed to a nonprotective reaction product that spalls from the sample. It was proposed that the lower ratio of BeO to C production in CO oxidation (eqn. [6]), as compared with CO<sub>2</sub> oxidation (eqn. [3]), results in excessive C (or Be<sub>2</sub>C) incorporation, and thus, a less protective film. Subsequent selected-area transmission electron microscope diffraction patterns by Scott confirmed that BeC<sub>2</sub> was in fact incorporated into the oxide during oxidation in CO.<sup>39</sup> Subsequent work on these alloys by Scott found that calcium acted to reduce oxidation rates by decreasing the extent of intergranular oxidation of the metal.<sup>40</sup>

### 3.18.4.2 Beryllides

Beryllium intermetallics are currently being considered as replacement materials for beryllium in demonstration fusion reactors. Although beryllium is commonly used as a neutron multiplier in the fusion blanket, its melting point is low (1285 °C) and the ITER demonstration reactor requires temperature in the 600–900 °C range. Possible replacements include beryllium–copper such as CuNiBe and TiBe<sub>2</sub>. These two intermetallics are representatives of the Laves

phases group C14 and C15. Phases in these groups include CrBe<sub>2</sub>, NbBe<sub>2</sub>, TaBe<sub>2</sub>, and VBe<sub>2</sub> and have been the subject of limited oxidation studies. Paine *et al.* tested the above phases in dry air for 100 h at temperatures up to 1426 °C.<sup>41</sup> Each was shown to have good oxidation resistance under these test conditions. However, the study was heavily biased toward the highest melting point compounds, of which TiBe<sub>2</sub> is one, and therefore, many phases were not examined because they did not appear promising for service above 1371 °C. In a separate study, Alves *et al.* investigated Ti beryllides, Be–5% Ti (Be<sub>12</sub>Ti), and Be–7% Ti, which was a two-phase system consisting of Be<sub>12</sub>Ti surrounded by Be.<sup>42</sup> From surface analytical experiment (X-ray emission and RBS) of samples oxidized at 800 °C for 1–4 h, it was found that the oxidation in the two-phase system was faster than in Be<sub>12</sub>Ti.

By far, the largest amount of information on any beryllide relates to ZrBe<sub>13</sub> and other zirconium-based beryllides. In experiments on powders, Ervin and Nakata found a protective BeO on ZrBe<sub>13</sub> and NbBe<sub>12</sub> between 900 and 1500 °C.<sup>43</sup> The oxidation rate for ZrBe<sub>13</sub> in 0.1-atm oxygen was parabolic and is presented in Figure 12. In comparison, the rates reported by Paine were much higher for air. Paine reported that the oxidation rate for ZrBe<sub>13</sub> in dry air (at 1537 °C) was 10 mg cm<sup>−2</sup> after 100 h and 6 mg cm<sup>−2</sup> for moist air after the same period.<sup>41</sup> The temperature dependence of the rate constants

from the Ervin data is shown in Figure 13 as an Arrhenius plot. As seen in this figure, two activation energies for oxidation ( $Q$ ) were observed. In the range of 1100–1400 °C,  $Q$  was determined to be  $5.6 \times 10^4$  J, while in the range between 1400–1500 °C,  $Q$  was

**Figure 12** Oxidation of  $\text{ZrBe}_{13}$  as a function of temperature in 0.1 atm  $\text{O}_2$ . Reproduced from Ervin G., Jr.; Nakata, M. M. *J. Electrochem. Soc.* **1963**, 110, 1103, with permission from The Electrochemical Society.

determined to be  $21.5 \times 10^4$  J. Similar results were found for  $\text{NbBe}_{12}$ ; however, for  $\text{NbBe}_{12}$ ,  $Q$  was constant over the entire temperature range examined and determined to be equal to  $13.0 \times 10^4$  J. Ervin and Nakata reported accelerating oxidation of  $\text{ZrBe}_{13}$  at lower temperatures in 0.1 atm oxygen (Figure 14), while  $\text{NbBe}_{13}$  was immune to this phenomenon. This observation was attributed to “fracture and disintegration of the metal phase causing a continual increase in the exposed metal surface area.” This phenomenon is known as pest and has been reported by several other authors.<sup>44–48</sup> Chou *et al.* reported that the susceptibility of  $\text{ZrBe}_{13}$  to pest is increased in the presence of moist air, although this finding is not uniform amongst other authors investigating Zr-based beryllides. In addition, Chou concluded that the formation of BeO-rich whiskers is important in the pest mechanism of beryllides, but did not report how they might form or why they cause disintegration.

The influence of Be additions on the high temperature oxidation of NiAl and TiAl-based intermetallics has been investigated by Hanrahan.<sup>49</sup> In TGA studies conducted from 800 to 1200 °C for 16 h in air, Be-modified NiAl containing 1, 2, or 5 at.% Be exhibited lower weight gain and comparable or slower oxidation rates than the pure binary material. In addition, the reaction kinetics in these

**Figure 13** Arrhenius plot from data in 5.4.2.1 showing the parabolic rate constant as a function of inverse temperature ( $K$ ) for  $\text{ZrBe}_{13}$  in 0.1 atm  $\text{O}_2$ . **Figure 14** Low-temperature (600–700 °C) oxidation of  $\text{ZrBe}_{13}$  in 0.1-atm  $\text{O}_2$ . Reproduced from Ervin G., Jr.; Nakata, M. M. *J. Electrochem. Soc.* **1963**, *110*, 1103, with permission from The Electrochemical Society.

experiments were equal to or slower than in NiAl. The surfaces of the Be-modified specimens showed minimal topography, with no evidence of the usual transient alumina phases grown on binary NiAl in this temperature range. From X-ray diffraction and surface analysis, it was found that oxidation did not result in formation of BeO at any of the temperatures. Rather, the presence of layers of  $\text{Al}_2\text{O}_3$  and ternary oxide phases, primarily  $\text{BeO} \cdot \text{Al}_2\text{O}_3$  (chrysoberyl), were observed. It was proposed that the formation of this phase prevents the growth of the transient alumina phases. Thus, lower weight gains and slower reaction kinetics were observed due to the rapid formation of the chrysoberyl phase followed by nucleation of  $\alpha$ -alumina at the scale-metal interface, rather than the formation of transient alumina phases

often observed to form on NiAl. In other studies, Be additions to Ti–Al–Cr-based alloys at 800 °C and 1000 °C in dry air resulted in the formation of a protective  $\text{BeAl}_2\text{O}_4$  spinel phase.<sup>50</sup> In moist air, only Ti–Al–Cr–Be alloys with a high Cr content (10–15 at.%) formed the protective  $\text{Be} \cdot \text{Al}_2\text{O}_4$  scale.

## 3.19.1 Introduction

### 3.19.1.1 Background

Uranium is a naturally occurring, and naturally radioactive, element whose predominant commercial interest lies in the ability of the  $^{235}\text{U}$  isotope to undergo nuclear fission with consequent release of large amounts of energy. Uranium metal was first

prepared in 1841 by Peligot using reduction of anhydrous  $\text{UCl}_4$  with potassium. Uranium is an f-block element and a member of the actinide family that has similar, but not identical, chemistry with other elements in its series. Its radioactive nature was not appreciated until 1891 when Becquerel first detected it; however, natural uranium is only mildly radioactive, emitting relatively low-energy  $\alpha$  and  $\beta$  radiation, while material that has been depleted in  $^{235}\text{U}$  can be 30–40% less radioactive than natural uranium.

The main health and safety concern with uranium is its chemical toxicity as a heavy metal, rather than its natural radioactivity, which is relatively easily contained. Prior to the discovery of its fissionable nature in 1938 by Hahn and Strassman, it was used in a number of small-scale applications, predominantly because it imparts an attractive orange color to pottery glazes and a characteristic yellow-green color to glass. Uranium is not a particularly rare element and occurs in greater abundance than, for example, mercury, silver, cadmium, and tungsten and has a similar abundance to molybdenum.<sup>1</sup>

### 3.19.1.2 Applications

The fissionable isotope  $^{235}\text{U}$  comprises about 0.7% of natural isotopic abundance with the majority of the balance consisting of  $^{238}\text{U}$ ;  $^{234}\text{U}$  is also naturally present, but in tiny amounts. By far, the major use of uranium is currently as a nuclear fuel in which the  $^{235}\text{U}$  percentage generally requires enrichment over the natural level, commercial light-water reactors typically being designed to operate with 3–5% of  $^{235}\text{U}$ . The energy released during nuclear fission is approximately 200 MeV per atom or about  $80 \text{ GJ g}^{-1}$  ( $^{235}\text{U}$ ); this is approximately equivalent to 2.7 tons of coal or 13.7 barrels of oil. At 33% thermal efficiency, a 1000 MW electrical generating station consumes about 1 ton of  $^{235}\text{U}$  per year (compared with about 3 000 000 tons of coal per year). Interestingly, coal contains trace quantities of uranium (and thorium, another radioactive element) at levels from 1 to 10 ppm. Thus, a 1000 MW coal-fired power station typically releases between 3 and 30 tons of uranium + thorium into the environment every year of operation: comparable in mass (although very considerably less so in radioactivity) to spent nuclear fuel.

Other applications include those where uranium's exceptional density ( $19.05 \text{ Mg m}^{-3}$ ) is advantageous; these include ballast and counterweights in aircraft and yachts, radiation shielding in medicine and industrial radiography, as well as military uses in defensive armor plating and high-kinetic energy armor-piercing ammunition. Commonly, depleted uranium (DU; typically  $<0.25\%$   $^{235}\text{U}$ , with a radiation level about 40% less than natural uranium) is used as it is a relatively cheap and abundant material with no other significant applications (the world inventory of DU is said to be over 1 million tons).

### 3.19.1.3 Metallurgy and Alloying

Uranium, unusually for a metallic element, has a room-temperature structure that is orthorhombic ( $\alpha\text{-U}$ ) below about  $670^\circ\text{C}$ , tetragonal ( $\beta\text{-U}$ ) from  $670$  to  $770^\circ\text{C}$ , and body-centered cubic ( $\gamma\text{-U}$ ) above about  $770^\circ\text{C}$ . The orthorhombic structure implies significant anisotropy in physical properties, and few alloying elements have significant, if any, room-temperature solubility. The mechanical properties of uranium are more akin to those of tungsten than of gold. Thus, cast commercial-purity uranium has yield and ultimate tensile strengths of, respectively, 200–250 and 600–700 MPa, comparable to austenitic stainless steels, with a ductility of about 25%. It has a ductile to brittle transition at about  $0^\circ\text{C}$ , where its impact strength and fracture toughness fall significantly.

The most common alloys of uranium are titanium ( $\sim 0.75\%$  Ti), niobium ( $\sim 2\text{--}7\%$  Nb), and molybdenum (up to 10% Mo). The alloys are hardenable by solid-solution heat treatment in the  $\gamma$ -phase region, then by quenching and aging to form second-phase particles. Room-temperature aged titanium-containing alloy has a yield stress (YS) of up to 600 MPa and ultimate tensile strength (UTS) of 1200 MPa, which can be increased to over 1200 and 1800 MPa respectively, with negligible ductility by aging at  $500^\circ\text{C}$ . The niobium-containing alloy has lower strength but improved ductility after aging. [Table 1](#) gives property data for some of the more common uranium alloys. In view of these relatively attractive mechanical properties, it has been mooted that uranium might constitute a valuable structural material for specific applications although the dual attributes of its mild radioactivity and relatively poor corrosion resistance are large barriers to any significant adoption.<sup>1</sup>

**Table 1** Properties of some uranium alloys; vacuum-annealed to ensure low hydrogen content

Alloy	Processing	YS (MPa)	UTS (MPa)	Elongation (%)	Corrosion resistance
Unalloyed U	Cast and $\beta$ -quenched	295	700	22	Poor
Unalloyed U	$\alpha$ -Rolled	270	720	31	Poor
U–0.75Ti	$\gamma$ -Quenched	650	1310	31	Fair
U–0.75Ti	$\gamma$ -Quenched, aged $450^\circ\text{C}$ , 6 h	1210	1660	$<2$	Fair

U–6.0Nb	$\gamma$ -Quenched	160	825	21	Good
U–10Mo	$\gamma$ -Quenched	900	930	9	Good
U–7.5Nb–2.5Zr	$\gamma$ -Quenched	540	850	23	Good

### 3.19.2 Aqueous Corrosion

#### 3.19.2.1 Thermodynamics

Uranium is an extremely active element and has a complex chemistry, showing all oxidation states from +2 to +6. In the absence of hydride formation, the Pourbaix diagram, [Figure 1](#), shows a significant domain of passivity due to the formation of  $\text{UO}_2$  as well as other, more complex, oxides. Importantly, thermodynamics predict that the passive oxide  $\text{UO}_2$  is susceptible to further oxidation (transpassive dissolution) at both low and high pH, forming soluble uranium species of valency 6; it also transforms to hydrated  $\text{UO}_3$  at intermediate pH. These reactions occur at a slow rate in humid air and, consequently,  $\text{UO}_2$  is not generally protective and the corrosion resistance of unalloyed uranium is poor. Where hydride formation is included in the thermodynamic diagram ([Figure 2](#)),  $\text{UH}_3$  formation is seen also to be stable, although in the presence of humid air the hydride forms only transiently further reacting to  $\text{UO}_2$  and water. Thus, in order to handle uranium without significant degradation, a dry-nitrogen glove-box atmosphere is required. Hydride formation can give rise to severe embrittlement and stress corrosion cracking phenomena, and finely divided uranium can spontaneously ignite and burn pyrophorically.

#### 3.19.2.2 Water

As predicted from the thermodynamic diagram, uranium reacts with water to form uranium dioxide, hydrogen, and uranium hydride. However, the hydride usually has only an ephemeral existence and reacts itself with water to form uranium dioxide and hydrogen. Reaction rates decrease with pH below 2, and it has been suggested that the solid products form by the inward diffusion of hydroxyl ions through the oxide.<sup>3</sup> The oxide is produced mainly as a nonadherent powder, and a linear rate law is obeyed.

Autoclave tests have demonstrated that the rate constant increases markedly with temperature up to at least 300 °C ([Figure 3](#)).<sup>4</sup> The corrosion rate is also influenced by dissolved gases in the water. In particular, the presence of dissolved oxygen decreases substantially the reaction rate<sup>4</sup> but makes the metal susceptible to crevice corrosion and pitting attack. The inhibition is most marked at lower temperatures, at which the oxygen solubility is highest and the hydrogen product is not sufficient to reduce the oxygen content locally. The oxygen could exert its influence by being adsorbed preferentially on the oxide<sup>5</sup> or by removing the disruptive influence of the formation of uranium hydride. An alternative view of such 'hydrogen effects' relates them to changes in the

**Figure 1** Pourbaix diagram for uranium (with hydride absent) at a metal ion concentration of  $10^{-5}$  M. Calculated with HSC: Chemistry, version 6.12; Outotec Research Oy: Finland, 2007.

**Figure 2** Pourbaix diagram for uranium (hydride present) at a metal ion concentration of  $10^{-5}$  M. Calculated with HSC: Chemistry, version 6.12; Outotec Research Oy: Finland, 2007.

**Figure 3** Oxidation rates of uranium in distilled water, air,  $\text{CO}_2$ , and CO as a function of temperature.

electrical properties of the oxide detected by impedance measurements during corrosion.<sup>6</sup>

Peretrukhin *et al.* studied the corrosion of uranium and its dilute alloys (<0.5% of Zr, Nb, and Ru) in water and bicarbonate aqueous solutions together with the effect of radiolytically generated hydrogen peroxide. No significant difference in corrosion rates for the alloys was found. Regarding the corrosion mechanism, U(III) was found to be rather unstable in neutral solutions and significant precipitation of  $\text{U}(\text{OH})_3$  occurred; no significant quantities of hydride or soluble U(III) species were found.<sup>7</sup>

The atmospheric oxidation kinetics for U(IV) to U(VI) were also studied,<sup>7</sup> where it was shown that U(IV) oxidation by atmospheric oxygen in the pH range 1.5–4.0 resulted in first-order kinetics with respect to uranium. Notably, an induction period for uranium (IV) accumulation was evident, after which the reaction accelerated. The reaction mechanisms differed in the two media: in weakly acid solutions, after the initial appearance of U(VI), evidence for disproportionation of the U(V) intermediate was found. Of mechanistic importance is the formation of a copolymer of U(IV) and U(VI), which at  $\text{pH} \geq 4$  prevents formation of U(V) and limits the oxidation rate. In the presence of hydrogen peroxide, the metallic uranium surface became transpassive and the corrosion rate increased by at least an order of magnitude.

Mechanical failure, which may be associated with stress corrosion as well as hydrogen pickup, has been observed for specimens of uranium<sup>8</sup> and various quenched alloys. For at least the alloys, it is enhanced by chloride ions<sup>9</sup> and is inhibited by cathodic polarization.<sup>10</sup> At higher temperatures, the only resistant metallic materials based upon uranium are alloys containing appreciable amounts of the  $\gamma$ -phase stabilizing elements, molybdenum, niobium, and zirconium,<sup>4</sup> the silicide  $\text{U}_3\text{Si}$ ,<sup>11</sup> and the aluminides. However, the alloys, as distinct from the intermetallic compounds, tend to fail suddenly by disintegration after long periods of exposure, possibly because of internal hydride formation.

The corrosion of DU metal in deaerated ground-water (similar to that at the proposed Yucca mountain nuclear waste repository in the United States) was studied at 90 °C with a view to investigate the rate and products of corrosion: that is,  $\text{UO}_2$ ,  $\text{UO}_{2+x}$ ,  $\text{UH}_3$ , and  $\text{H}_2$ .<sup>12</sup> After exposure over an 81-day period, X-ray powder diffraction revealed the presence of  $\text{UO}_2$  and higher oxides: that is,  $\text{UO}_{2+x}$ ; however, no hydride was detected. The corrosion rate of the uranium metal in the water at 90 °C was determined by measuring the evolution of hydrogen gas, and this revealed a corrosion rate of  $1.42 \text{ mg cm}^{-2} \text{ h}^{-1}$ . This value agreed extremely well with a published Arrhenius-type expression for the corrosion rate of uranium metal in water that had been obtained from a compilation of experimental data<sup>13</sup>:

$$\ln k = 22.34 - \frac{7989}{T}$$

where  $T$  is the absolute temperature (K) and  $k$  is the corrosion rate ( $\text{mg cm}^{-2} \text{ h}^{-1}$ ).

### 3.19.2.3 Atmospheric Corrosion

Uranium tarnishes readily in the atmosphere at room temperature. Electropolishing inhibits the process, while etching in nitric acid activates the surface. Uranium dioxide and hydrated  $\text{UO}_3$  are the principal solid products, although uranium hydride may have a transitory existence. The corrosion is enhanced by water vapor and hence is governed by the humidity conditions.<sup>14</sup> However, the presence of oxygen markedly inhibits attack by water vapor.<sup>5</sup> Danon *et al.* undertook a desorption study of the surface chemistry of chemisorbed species on atmospherically oxidized uranium.<sup>15</sup> The main identified species included water (in different binding forms) and hydrogen. The latter originates from the water–uranium oxidation reaction, which produces uranium dioxide and two types of hydrogen: a near-surface hydride and a surface-chemisorbed form

that desorbs at a lower temperature than the hydride. Water was found to be bound in four forms: (a) a reversibly chemisorbed molecule, (b) tightly bound water molecules, (c) strongly bounded hydroxyl groups and, the most stable (d) a complex water–carboxylate. Hydrogen desorption was also studied, with two main peaks found, one being ascribed to the desorption of lattice hydrogen and the higher temperature peak being related to the decomposition of hydrides.

The corrosion of uranium in water vapor was studied between 50 and 90 °C and from 32% to 86% RH using thermogravimetry.<sup>16</sup> The results show three stages in the uranium–water oxidation reaction. Thus, a rapid initial reaction is followed by a reducing rate and, in the third stage, the corrosion reaction proceeds linearly with an activation energy of about  $43 \text{ kJ mol}^{-1}$  at 74.7% RH.

### 3.19.2.4 Effects of Water Radiolysis

The effect of  $\alpha$ -radiolysis of water on the corrosion potential of  $\text{UO}_2$  has been measured where the cell construction allowed the source to be brought within 30 mm of the  $\text{UO}_2$  electrode.<sup>17</sup> Oxidizing conditions were provided at the  $\text{UO}_2$  surface, and over a period of 30 h, the main process occurring appeared to be the catalytic decomposition of  $\text{H}_2\text{O}_2$  to  $\text{H}_2\text{O}$  and  $\frac{1}{2}\text{O}_2$  with some oxidation of the  $\text{UO}_2$ . The oxidation of uranium by water was studied by Fuller *et al.*<sup>18</sup> using infrared and sorption analysis. Oxidation occurred in cycles forming laminar layers of oxide that tend to spall off because of the strain at the oxide–metal interface. The reaction rate is directly proportional to the amount of adsorbed water on the oxide product, and transport was rapid through the open hydrous product. Dehydration of the hydrous oxide irreversibly forms a more inert oxide which cannot be rehydrated to the degree that prevails in the original hydrous product by uranium oxidation with water. An anomalous temperature dependence was observed for the oxidation of oxycarbide layers on the surface of uranium metal.<sup>19</sup> Normally, oxidation or corrosion reactions are expected to proceed more rapidly as water temperature increases, but the removal of the outermost atomic layers of carbon from uranium oxycarbide by oxygen reproducibly proceeds at a much faster rate at 25 °C than at 280 °C.

The kinetics of  $\text{UO}_2$  fuel oxidation by the products of  $\gamma$  radiolysis of water have been studied by Sunder *et al.* as a function of absorbed dose rate.<sup>20</sup> The radical species formed during water radiolysis are much more effective in promoting  $\text{UO}_2$  oxidation

than molecular oxidants, howsoever formed. Thus,  $\text{UO}_2$  oxidation during  $\gamma$  radiolysis of water occurs in two stages: (a) the formation of a thin layer of  $\text{UO}_{2+x}$  (of composition close to  $\text{UO}_{2.33}$ ); and (b) the subsequent oxidative dissolution of this surface layer to produce soluble U(VI) species and secondary phases, probably hydrated schoepite ( $\text{UO}_3 \cdot x\text{H}_2\text{O}$ ), on the  $\text{UO}_2$  substrate. The first stage occurs in the potential range  $-500 \text{ mV} < E_{\text{corr}} < -100 \text{ mV}$  (versus SCE). The second stage starts around  $E_{\text{corr}} \sim -100 \text{ mV}$  and eventually achieves steady state at a value of  $E_{\text{corr}}$  determined by the  $\gamma$  dose.

### 3.19.2.5 Galvanic Corrosion

Galvanic corrosion reports have emerged from two sources. In the first,<sup>21</sup> the chemical compatibility of uranium carbides and Cr–Fe–Ni alloys was discussed. Evaluation was by thermodynamic modeling and experimental phase studies. Two reaction temperatures (700 and 1000 °C) were used to simulate normal and overtemperature operation of advanced liquid metal fast-breeder reactor fuel-cladding couples. In the second, McIntyre *et al.*<sup>22</sup> coupled depleted U–0.75% Ti to aluminum, magnesium, or mild steel in synthetic seawater. The galvanic current was monitored with time. Gravimetric measurements, polarization resistance measurements, and galvanic currents were monitored over extended periods of time in order to detect changes in galvanic corrosion behavior. Good agreement was obtained for corrosion rates determined electrochemically and those obtained from gravimetric methods.

Galvanic corrosion is also important in metallic coatings applied as protective barriers in uranium. For example, electroplated nickel is an excellent corrosion-resistant barrier; however, when it is subject to localized attack (i.e., pitting), corrosion of uranium occurs at the coating–substrate interface.<sup>23</sup> Rapid failure of the coating tends to ensue because of the volume increase caused by development of uranium corrosion products that causes undermining and cracking of the coating.

### 3.19.2.6 Stress Corrosion Cracking

Uranium alloys are susceptible to stress corrosion cracking (SCC) and knowledge of the surface stresses involved are essential. In an uncoated U–Ti alloy, these have been found to be relatively large and compressive at 365 MPa, but the presence of nickel or zinc coatings led to much smaller compressive stress.<sup>24</sup> The stress corrosion behavior of U–7.5Nb–2.5Zr

in oxygen and hydrogen gases over a temperature range of  $-20$  to  $100^\circ\text{C}$  under pressures varying from  $0.3 \times 10^{-6}$  to  $0.15 \text{ MPa}$  has been analyzed using a fracture mechanics approach.<sup>25</sup> SCC mapping and cracking kinetics were determined as functions of stress intensity factor, temperature, and pressure. It was found that the mechanism responsible for SCC varied with the experimental conditions used.

Powell and his coworkers have explored the hydrogen embrittlement problem associated with uranium alloys.<sup>26,27</sup> Looking at the internal hydrogen embrittlement of  $\gamma$ -stabilized uranium alloys (i.e., containing Mo, Nb), they found that the tensile ductility decreased only slightly with increasing hydrogen content up to a critical hydrogen concentration, above which the tensile ductility dropped to nearly zero.<sup>26</sup> The critical hydrogen content for the ductility loss increased with increasing hydrogen solubility in the alloy. The fracture surfaces were not characteristic of those found under conditions of SCC. Hydrogen embrittlement of U–5.7Nb alloy showed enhanced microvoid coalescence fracture with loss of tensile ductility for hydrogen concentrations less than 23 mg hydrogen per gram of metal, the alloy having been solution-annealed at  $800^\circ\text{C}$  and water-quenched.<sup>27</sup> However, specimens with 36 mg hydrogen per gram of metal had much lower ductilities and exhibited a new, possibly hydride, phase which was associated with brittle transgranular fracture when this phase has a lenticular morphology extending well across the parent metal grains.

The interactions between aqueous corrosion and mechanical deformation in uranium and alloys involve complex processes of mechanical damage. Various mechanisms are possible for the observed reduction in ductility/fracture toughness during corrosion, including SCC (e.g., via brittle film fracture or film-induced cleavage), hydrogen embrittlement (e.g., via classical mechanisms or by hydride formation), as well as others. Bussiba *et al.*<sup>28</sup> undertook a series of mechanical tests in order to determine the influence of specific mechanisms on the performance of lean uranium alloys (U–0.1Cr and U–0.75Ti) in water and at controlled levels (30, 40, and 80%) of RH. Crack growth rates of between  $10^{-5}$  and  $10^{-9} \text{ m s}^{-1}$  were determined at a stress intensity corresponding to  $16 \text{ MPa m}^{1/2}$ . Cracking appeared to operate discontinuously with trigger events corresponding to acoustic noise generation. In all conditions (i.e., humid air or immersion), surface hydride formation was observed; however, their role in the fracture process could not be confirmed. However,

the rather rapid crack growth velocities seem to imply a triggering mechanism that involves hydrogen embrittlement.

### 3.19.3 Gases at High Temperatures

#### 3.19.3.1 Carbon Dioxide and Carbon Monoxide

The solid corrosion products resulting from reaction with carbon dioxide and carbon monoxide are uranium dioxide, uranium carbides, and carbon.<sup>29</sup> The major reaction with carbon dioxide results in the formation of carbon monoxide and  $\text{UO}_2$ :

Uranium can also form the carbide with an overall reaction:

The formation of uranium carbide must involve carbon transfer from the gas phase and probably occurs via reactions of carbon monoxide with the metal through pores of the oxide scale. This transfer could occur by direct reaction or via the thermal decomposition of the gas to produce carbon dioxide, which may then react subsequently with uranium, thus forming the carbide:

Diffusion studies on  $\text{UO}_2$  demonstrate that oxygen ions are the major diffusing species in the oxide and, therefore, that the oxide grows by the inward passage of oxygen.<sup>30</sup> Volume changes associated with the oxidation lead to large stresses in the oxide and subsequently to the formation of solid products in the form of powders and/or cracked porous scales.

At the temperatures of interest, a linear rate law is quickly established, and the rate-determining step is believed, in general, to be diffusion of oxygen ions through a thin layer of adherent oxide of constant average thickness at a given temperature. For carbon dioxide, the rate constant (Figure 3) increases steadily with temperature until there is a sudden increase in rate, together with some selfheating from the high heat of reaction, at or near the  $\beta$ - $\gamma$  phase transition in the metal (780 °C); at higher temperatures there is little or no dependence of reaction rate on temperature up to 1000 °C. The majority of the oxide forms as either a nonadherent powder (the particle size of which increases with temperature) or, at the highest temperatures, as a cracked adherent scale. The formation of scale accounts for the lack of temperature dependence

for the rate constant at the highest temperatures and could result either from sintering of the oxide or, more probably, from the growth stresses being relieved by plastic deformation of the oxide and/or the underlying metal, rather than rupture of the oxide. At the highest temperatures, the rate-determining step might be gaseous diffusion through the porous scale.<sup>31</sup> The presence of small amounts of water vapor (greater than 100 ppm) and oxygen (greater than 10 ppm) enhances the attack significantly at the lower temperatures of 400–500 °C,<sup>29</sup> and under these conditions preferential attack is frequently observed at carbide inclusions in the metal.<sup>32</sup> Major alloy additions of silicon (greater than 3.8%) impair oxidation resistance at all temperatures, whereas additions of copper (1%), titanium (5–10%), and molybdenum (10–15%) decrease the rates, but only at the higher temperatures.<sup>33</sup> The beneficial influence of copper is associated with the enrichment of the element at the metal–oxide interface as the  $\text{UCu}_5$  phase.<sup>34</sup> The mechanisms responsible for the effects of the other alloying elements have not been firmly established, but can be attributed to changes in the physical defects and thicknesses of the adherent oxide and, hence, in its protective properties.

The oxidation rates in carbon monoxide (Figure 3) are less than those for carbon dioxide. They increase steadily with temperature up to 800 °C but then decrease markedly by a factor of 100 up to 1000 °C. The decrease in rate can be attributed to the dissociation of carbon dioxide at higher temperatures and to its consequently low partial pressures.

#### 3.19.3.2 Air

Thermal oxidation of uranium dioxide proceeds in air and results ultimately in the formation of  $\text{U}_3\text{O}_8$  at temperatures above 200–300 °C. The lower oxides may also be formed as intermediaries and at lower temperatures. The volume change associated with formation of  $\text{U}_3\text{O}_8$  is greater than for uranium dioxide and, as with carbon dioxide, leads to a linear rate law being established. This gives significantly more rapid oxidation kinetics<sup>35</sup> by comparison with the behavior in carbon dioxide (Figure 3). The rapid reaction rate, coupled with the large enthalpy of reaction, leads to an appreciable selfheating of specimens and an associated increase in reaction rate. In this situation, the supply of oxygen from the air can be rate-determining. The susceptibility of the metal to selfheating increases with the surface area-to-volume ratio of components, and powders may spontaneously ignite at room temperature.<sup>36</sup> However, large blocks

of metal are not normally liable to selfheating until 400–600 °C and then need an external heat source to maintain the situation. Alloy additions of molybdenum (5–15%) markedly reduce reaction rates.<sup>10,37</sup> Minor additions of other elements may either enhance or reduce the susceptibility to ignition<sup>38</sup> (e.g., aluminum or copper, respectively).

### 3.19.3.3 Steam

The mechanisms of corrosion by steam are similar to those for water up to 450 °C, but at higher temperatures are more closely related to the behavior in carbon dioxide. Studies at 100 °C have demonstrated that uranium hydride is produced during direct reaction of the water vapor with the metal and not by a secondary reaction with the hydrogen product. Also, at 100 °C it has been shown that the hydride is more resistant than the metal.<sup>3</sup> Inhibition with oxygen reduces the evolution of hydrogen and does not involve reaction of the oxygen with the uranium.<sup>6</sup> Above 450 °C, the hydride is not stable and hydrogen is released directly to the gas phase. Also, the cohesion and protection provided by the uranium dioxide increase with the formation of a dense scale, at least for short times at the highest temperatures. As a consequence, the extent of reaction after a period greater than 100 min is at a maximum at 300–400 °C with a rate of weight gain of  $10^3 \text{ g m}^{-2} \text{ h}^{-1}$ . The reaction rate increases only slowly with temperature from 500 to 1200 °C, although one piece of work reported a marked increase in attack near the  $\beta$ – $\gamma$  transition in the metal,<sup>39</sup> analogous to that obtained in carbon dioxide. A parabolic rate law has been found to apply at temperatures of 500–1200 °C for periods of 30 min to 6 h,<sup>40</sup> although another work indicates that this law is established for only 1–2 h above 880 °C and that a linear law generally applies.<sup>39</sup> It follows that for a period of 1–2 h, the extent of corrosion in steam straddles that for carbon dioxide, being greater at temperatures less than 700 °C and comparable or less at higher temperatures.

The oxidation rates of uranium in steam were measured between 200 and 550 °C. Arrhenius-type behavior was observed below 300–350 °C, with activation energies of 47 kJ mol<sup>−1</sup> for U foil below 350 °C and 58 kJ mol<sup>−1</sup> for U bar below 300 °C.<sup>41</sup> However, a significant rate reduction was observed at higher temperatures. In all cases, the oxidation products were uraninite-structured  $\text{UO}_{2-x}$  compounds. Non-adherent oxide layers were formed on bar samples below ~300 °C, but became increasingly adherent at higher temperatures. Similarly, the oxide layers on foil

samples below ~350 °C had highly porous cellular structures, whereas the layers formed at higher temperatures were significantly denser. For both materials, the fall in oxidation rate above 300–350 °C was attributed to reduced steam ingress to the underlying metal caused by the increasingly protective surface oxide.

Oxidation of  $\text{UO}_2$  by pure steam at pressures of 7 and 70 atm and 500 and 600 °C was measured using thermogravimetry.<sup>42</sup> Linear kinetics were observed, which varied as the square root of the steam pressure, and is consistent with initial rates extrapolated from higher temperature experiments in 1-atm steam. At temperatures characteristic of normal operation of defective fuel rods, the rate of hydrogen production by thermal oxidation of the fuel in steam is small compared to that due to cladding corrosion. The presence of  $\text{H}_2$  in the steam was found to have much greater influence on reducing the rate of oxidation  $\text{UO}_2$  than on oxidation of cladding.

An experimental study of  $\text{UO}_2$  oxidation in pure steam and in  $\text{H}_2\text{O}/\text{Ar}/\text{H}_2$  mixtures was conducted using a thermal balance at 1 atm in the temperature range 1000–1350 °C.<sup>43</sup> Two surface reaction models were assumed. A phenomenological model assumes that the reaction rate is proportional to the difference between the  $[\text{O}]$  in the solid and the equilibrium  $p\text{O}_2$  in the ambient gas. The results show that this model is a poor fit for oxidation in steam, but is good for  $\text{H}_2\text{O}/\text{Ar}/\text{H}_2$  mixtures. A mechanistic model, based on the assumption that the rate-controlling step was water dissociation at the solid surface, provides a very good fit to all the data. Thus, as long as the pressure is 1 atm, either model can be used to predict nuclear fuel oxidation in severe loss of coolant accidents because the ambient gas invariably contains hydrogen produced by Zircaloy corrosion. However, the kinetics of oxidation in high-pressure steam–hydrogen mixtures are still uncertain. Evidence of uranium volatilization and preferential etching at the grain boundaries at high temperatures were observed.

## 3.19.4 Corrosion Processes

### 3.19.4.1 Protective Coatings

Uranium may be anodized in ethylene glycol containing ammonia and this produces oxide films that are predominantly uranium dioxide in composition<sup>44</sup> and which show considerable resistance to atmospheric corrosion. During film formation at constant current, the voltage rises steeply to a plateau giving predominantly crystalline films. After reaching a

second voltage plateau, the films are largely amorphous. The rate of oxidation during the initial voltage rise, assuming maximum current efficiency, is between 1.6 and 2.0 nm V<sup>-1</sup>.

Metallic and organic-based coatings have been developed to protect uranium from oxidation at low and high temperatures. The work on metallic coatings has covered intermetallic compounds and solid solutions of uranium with aluminum, zirconium, copper, niobium, nickel, and chromium.<sup>45</sup> Aluminum- and zirconium-based coatings<sup>46,47</sup> can be particularly effective in reducing attack over an extended range of temperature. Also, nickel plating can provide protection against atmospheric corrosion.<sup>48</sup> Work on organic coatings has demonstrated that they can enhance resistance to atmospheric corrosion.<sup>49,50</sup> This behavior is attributed to the loss of the inhibiting action of oxygen due to water vapor permeating the coatings more readily than oxygen.

Aluminum, zinc, magnesium, Al-Zn, Al-Mg, nickel, titanium, TiN, and Al/TiN coatings have all been applied by the arc plasma physical vapor deposition (PVD) technique to a DU alloy for corrosion protection assessment.<sup>51</sup> The as-deposited specimens were examined by scanning electron microscopy for surface morphology and tested for adhesion. Electrochemical polarization tests and immersion tests were conducted in aerated 3.5 wt% NaCl solution. Results of electrochemical polarization in 3.5% NaCl solution and observations after long-term exposure tests indicated that both Al-Zn and Al-Mg alloys appear to be the best sacrificial coating materials for improving the corrosion resistance of DU-0.75 Ti.

The effect of various oxyanions (MoO<sub>4</sub><sup>2-</sup>, PO<sub>4</sub><sup>3-</sup>, VO<sub>4</sub><sup>3-</sup>, MnO<sub>4</sub><sup>-</sup>, SiO<sub>4</sub><sup>4-</sup>, and WO<sub>4</sub><sup>2-</sup>) on the corrosion inhibition of U-0.75Ti alloy in nitric acid has been studied.<sup>52</sup> Results indicate that chemical or electrochemical activation of the uranium in 0.1 M HNO<sub>3</sub> + 0.025 M molybdate can lead to the formation of a rudimentary conversion coating. Building on this finding, molybdenum oxide-based coatings were formed on U-0.75Ti alloy<sup>53</sup> using nitric acid in order to activate the metal surface. Successful coatings were produced of the order of 650 nm in thickness. After aging, the coated samples showed an ennobled potential of around 400 mV and a reduced corrosion current density of around 10 times.

### 3.19.4.2 Irradiation Effects

The behavior of irradiated uranium has been studied mainly with respect to the release of fission products

during oxidation at high temperatures.<sup>54</sup> The fission products most readily released to the gas phase are krypton, xenon, iodine, tellurium, and ruthenium. The release can approach 80–100%. For ruthenium, it is dependent upon the environment and only significant in the presence of oxygen to form volatile oxides of ruthenium.

Studies of the influence of irradiation on the kinetics of oxidation have been confined to postirradiation work. In general, prior irradiation increases reactivity, although there are considerable inconsistencies in the enhancements obtained.<sup>17,54,55</sup> The effects can be derived from an increased surface area associated with the swelling voids produced in the metal by the irradiation, and can also probably arise to a lesser extent from chemical effects of the fission products.

The postirradiation examination of two uranium aluminide fuel plates exposed to aqueous corrosion showed failure due to pinhole corrosion during irradiation to about 76% of the maximum burn-up limit.<sup>56</sup> It was thought that the cladding failed by pitting corrosion initiated at preexisting pits at a hot spot. Fuel plate material was washed out through these pinholes due to aqueous corrosion and erosion. Egert<sup>57</sup> also looked at corrosion of coated uranium and found corrosion occurring at defects present in the coating. An equation was derived to predict the extent of substrate corrosion, given the number of defects per unit area and knowledge of the corrosion kinetics of the substrate.

### 3.19.4.3 Corrosion and Dissolution of UO<sub>2</sub>

As noted earlier, uranium dioxide is susceptible to transpassive dissolution to soluble uranium species at low and high pH and at sufficiently high potentials caused by the presence of oxygen in air, or of strongly oxidizing peroxide or radical species formed as a result of water radiolysis. At intermediate potentials, UO<sub>2</sub> may be oxidized to UO<sub>2+x</sub> or hydrated UO<sub>3</sub>. In order to suppress this oxidation, the effects of dissolved hydrogen on the aqueous corrosion of uranium dioxide (UO<sub>2</sub>) under nuclear waste disposal conditions were studied.<sup>58</sup> Measurements of the corrosion potential ( $E_{\text{corr}}$ ) indicate that the oxidation of dissolved hydrogen on noble-metal particles polarizes the UO<sub>2</sub> nuclear fuel surface to reducing potentials (–300 to –400 mV vs. SCE); that is, to  $E_{\text{corr}}$  values more negative than those observed under anoxic (argon-purged) conditions (–200 mV vs. SCE). Thus, noble-metal particles incorporated within UO<sub>2</sub> act catalytically to oxidize H<sub>2</sub>. It is the galvanic coupling of these

particles to the  $\text{UO}_2$  matrix that lowers the corrosion potential, thereby preventing oxidation of the fuel surface.

### 3.19.4.4 Uranium in the Environment

Corrosion of anthropogenic uranium in natural environments is not well understood, but is important for determining potential health risks and mobility in the environment. Buck *et al.* conducted studies of a site in the southwestern United States containing DU that has been weathering for approximately 22 years.<sup>59</sup> The main products of corrosion were found to be schoepite ( $(\text{UO}_2)_4\text{O}(\text{OH})_6 \cdot 6(\text{H}_2\text{O})$ ) and meta-schoepite ( $\text{UO}_3 \cdot 2(\text{H}_2\text{O})$ ), and occur on their own, mixed with clay/silt aggregates, or as coatings upon soil grains. It appeared from this study that local soil geomorphology and chemistry at this site limit uranium mobility and decreases potential health risks. However, changes in land use and/or climate could increase uranium mobility.

There is considerable concern over the use of dense kinetic energy projectiles containing DU in the battlefield and the consequent spread of uranium into the environment. The degradation of a DU penetrator shot in battle in Western Kosovo in 1999 and collected from there in June 2001 was studied.<sup>60</sup> Corrosion products on the surface were confirmed as  $\text{UO}_2$ , with the possible presence of other more oxidized uranium forms, such as  $\text{U}_3\text{O}_8$  and  $\text{UO}_3 \cdot 2(\text{H}_2\text{O})$ . Raman spectra from the surface shows evidence for mobile  $\text{UO}_2^{2+}$  uranyl ions. It can be concluded, therefore, that such projectiles will, in the environment, progressively release mobile uranium species.

In the United Kingdom, the testing of armor-piercing DU 'penetrators' has resulted in the deposition of DU in the sediments of the Solway Firth. Handley-Sidhu *et al.* undertook an investigation of this material by simulating Solway Firth sediments under variable conditions of salinity to study the impact of the corroding DU on the environment, including the microbial population.<sup>61</sup> Under suboxic conditions, the average corrosion rates were  $0.056 \text{ g cm}^{-2} \text{ year}^{-1}$ , implying that complete corrosion of a 120-mm penetrator would take approximately 540 years. Under sulfate-reducing conditions, corrosion ceased because of passivation of the surface. Corroding DU resulted in more reducing conditions and decreased microbial diversity as indicated by DNA sequencing and phylogenetic analysis. Since few uranium species were measured in the sediments adjacent to the DU projectiles, it must be assumed that U was transported

into the surrounding environment through dissolution of  $\text{U(VI)}$ , with subsequent interactions resulting in the formation of secondary uranium species in the sediment.

### Glossary

**Sputter deposition** Sputter deposition is a physical vapor deposition (PVD) method of depositing thin films by sputtering, that is, ejecting material from a target or source, which then deposits onto a substrate – for example, a silicon wafer.

**Amorphous alloy** An amorphous alloy is a metallic material with a disordered atomic-scale structure. In contrast to most metals, which are crystalline and therefore have a highly ordered arrangement of atoms, amorphous alloys are noncrystalline.

**X-ray photoelectron spectroscopy (XPS)** XPS is a quantitative spectroscopic technique that measures the elemental composition, empirical formula, chemical state, and electronic state of the elements that exist within a material. XPS spectra are obtained by irradiating a material with a beam of aluminum or magnesium X-rays while simultaneously measuring the kinetic energy (KE) and number of electrons that escape from the top 1–10 nm of material being analyzed.

**Rutherford backscattering spectroscopy (RBS)** RBS is an analytical technique used in materials science. Sometimes referred to as high-energy ion scattering (HEIS) spectroscopy, RBS is used to determine the

structure and composition of materials by measuring the backscattering of a beam of high energy ions impinging on a sample.

### Abbreviations

**RBS** Rutherford backscattering spectroscopy

**XPS** X-ray photoelectron spectroscopy

### 3.20.1 Corrosion of Amorphous Alloys

Amorphous alloys have been attracting much attention as a new class of metallic materials with excellent physical, mechanical, and chemical properties since their introduction in the late 1960s. The corrosion resistance of amorphous alloys is remarkable and some amorphous alloys are immune even to concentrated hydrochloric acids. Much interest has also been seen in amorphous alloy electrode materials due to their superior electrocatalytic properties as well as high durability, originating from high corrosion resistance. The synergistic effect of various alloying elements homogeneously mixed at the atomic level, in addition to the structurally metastable nature, contributes to the superior chemical properties.

It was believed until the late 1980s that rapid quenching with a quenching rate of more than  $\sim 10^5$  K s<sup>-1</sup> is

required to develop amorphous alloys. During this period, amorphous alloys were produced mostly by melt-spinning and physical vapor deposition (PVD) methods, including sputter deposition. Laser treatment of the alloy surface, as well as ion implantation, was used to develop amorphous alloy surfaces on bulk metallic substrates. In the late 1980s, amorphous alloys with extremely high glass-forming ability were discovered, and bulk amorphous alloys, usually referred to as bulk metallic glasses, are now available in many alloy systems by a conventional casting process. Extremely high glass-forming ability is attained in multicomponent alloy systems with large atomic size ratios of more than 12% and with negative heats of mixing. The discovery of bulk metallic glasses has eliminated the size limitation of amorphous alloys, and their practical importance has been significantly enhanced. Here, corrosion behavior of a range of amorphous alloys, including bulk metallic glasses, is outlined, together with nanocrystalline metallic materials. Interest has also been shown in nanocrystalline alloys due to their enhanced mechanical strength. The influence of nanocrystalline precipitates in an amorphous matrix on corrosion behavior of amorphous alloys will also be discussed here.

### 3.20.1.1 Examples of Corrosion-resistant Amorphous Alloys

Great interest in the corrosion resistance of amorphous alloys was initiated by the early work of Hashimoto and coworkers, which revealed the very high corrosion resistance of iron-metalloid alloys containing chromium even in aggressive hydrochloric acid solutions.<sup>1,2</sup> Results of corrosion tests for the amorphous Fe-10 at.% Cr-13 at.% P-7 at.% C alloy (alloy composition hereafter denoted as Fe-10Cr-13P-7C) and crystalline type-304 stainless steel are shown in Figure 1.<sup>1</sup> The melt-spun amorphous Fe-10Cr-13P-7C alloy reveals no measurable corrosion even in 1 mol dm<sup>-3</sup> HCl solution, while the corrosion rate of type-304 stainless steel increases with the increase in the concentration of HCl, greater than 10 mm s<sup>-1</sup> in 1 mol dm<sup>-3</sup> HCl solution. The amorphous Fe-10Cr-13P-7C alloy is spontaneously passive in HCl solution, and anodic polarization of this alloy does not induce pitting corrosion. The corrosion resistance of Fe-Cr-metalloid alloys was further improved by the addition of molybdenum.<sup>3-6</sup> Amorphous alloys containing sufficient amounts of both chromium and molybdenum were spontaneously passive even in concentrated HCl solution at elevated temperatures.<sup>6</sup>

**Figure 1** Example of the greatly enhanced corrosion resistance in 1 mol dm<sup>-3</sup> hydrochloric acid at room temperature of a Fe-based metallic glass (Fe-10Cr-13P-7C) compared to a crystalline, type-304 stainless steel alloy (Fe-18Cr-8Ni).<sup>1</sup>

In addition to Fe-based amorphous alloys, corrosion-resistant nickel-based amorphous alloys were discovered in the late 1980s. Amorphous Ni-based alloys containing 20 at.% or more tantalum were immune to corrosion in boiling 9 mol dm<sup>-3</sup> HNO<sub>3</sub> solution and maintained metallic luster.<sup>7</sup> Ni-Nb alloys containing 40–60 at.% niobium were also highly corrosion-resistant; their corrosion rates were as low as ~1 μm year<sup>-1</sup> in boiling 9 mol dm<sup>-3</sup> HNO<sub>3</sub> solution. Amorphous Ni-Nb and Ni-Nb-Cr alloys were spontaneously passive in 0.1 mol dm<sup>-3</sup> H<sub>2</sub>SO<sub>4</sub> solution, but transpassive dissolution occurred at high anodic potentials.<sup>8</sup> The amorphous Nb-valve metal alloys were also highly corrosion-resistant in hot concentrated phosphoric acid solution as well as in boiling sodium hydroxide solution.<sup>9,10</sup> The addition of small amounts of phosphorus enhances its glass-forming ability as well as its corrosion resistance.<sup>11-16</sup> The role of phosphorus in improving the corrosion resistance of amorphous alloys will be described later.

Most of these corrosion studies were performed using melt-spun amorphous alloy ribbons. In the late 1980s PVD methods, including sputter deposition, were introduced to produce corrosion-resistant amorphous alloys. One of the successful applications of this technique is an aluminum alloy system. The solid solubility of many alloying elements in aluminum at equilibrium is very limited, usually less than a

few atomic percent. None of the existing commercial aluminum alloys have good resistance against localized corrosion. Amorphous Al alloys containing supersaturated alloying elements, including molybdenum, tungsten, chromium, copper, and tantalum, show markedly improved pitting corrosion resistance.<sup>17–27</sup> Some amorphous Al alloys display good corrosion resistance even in hydrochloric acid solutions.<sup>28–30</sup> An example of improved pitting potential by the addition of molybdenum and tungsten is shown in **Figure 2**. The pitting potential of crystalline high-purity aluminum is  $\sim -0.7$  V versus SCE in a borate buffer solution containing  $0.1 \text{ mol dm}^{-3}$  NaCl. The addition of molybdenum ennobles pitting potential by more than one volt, with the addition of tungsten shifting the potential in a more positive direction.<sup>22</sup>

Amorphous alloys with ideally high corrosion resistance, consisting only of corrosion-resistant elements, were developed in the 1990s. Sputter-deposited Cr–X, Mo–X and W–X alloys, in which X denotes Ti, Zr, Nb, or Ta, were shown to be spontaneously passive in concentrated hydrochloric acid.<sup>31–44</sup> The extremely high stability of homogeneous double oxyhydroxides of  $\text{Cr}^{3+}$  and valve metal cations is responsible for the extraordinary corrosion resistance of Cr-valve metal alloys.<sup>45–48</sup>

Intensive studies have recently been conducted on the corrosion behavior of bulk metallic glasses due to

their wide range of potential applications. Bulk metallic glasses with extremely high corrosion resistance even in hydrochloric acid solutions have also been developed in Fe-based and Ni-based alloy systems. Bulk metallic glasses of Fe–Cr–Mo–C–B with and without phosphorus were synthesized over a wide composition range by copper mold casting, and showed high corrosion resistance in concentrated hydrochloric acid with corrosion rates in the range of  $10^3$  to  $10^2 \text{ mm year}^{-1}$ .<sup>49</sup> Bulk Ni-based glasses, containing Nb, Ta, Cr, and Mo in addition to phosphorus, are resistant in concentrated hydrochloric acid.<sup>50,51</sup>

### 3.20.1.2 Mechanism of Extremely High Corrosion Resistance

It was believed that extremely high corrosion resistance of some amorphous alloys is a consequence of the rapid formation of uniform passive films without weak points and with a high concentration of corrosion-resistant alloying element species in the thin passive films. As mentioned above, some amorphous alloys are immune even in concentrated hydrochloric acid. Such excellent corrosion resistance is not achieved by practical crystalline metals and alloys. Single-phase amorphous alloys are structurally and compositionally homogeneous, free from metallurgical heterogeneities such as grain boundaries, second phases, precipitates, inclusions, and segregations. In crystalline alloys, corrosion is often initiated preferentially at such heterogeneous sites. The compositionally uniform nature of amorphous alloys is a key to the coverage of the entire surface of a metallic substrate by a highly protective thin passive film to protect the alloy from severe corrosive attack.

The rapid formation of a highly protective passive film on amorphous alloys was demonstrated in an iron–chromium alloy system.<sup>52</sup> The high corrosion resistance of chromium-containing crystalline and amorphous alloys is attributed to the formation of passive films highly enriched in trivalent chromium species. For instance, immersion of amorphous Fe–10Cr–13P–7C alloy in  $1 \text{ mol dm}^{-3}$  HCl solution for 1 week gives rise to the formation of a passive film consisting exclusively of hydrated chromium oxyhydroxide,  $\text{CrO}_x(\text{OH})_{3-2x}$ .<sup>53</sup> Although chromium-enriched passive films are formed on both crystalline and amorphous chromium-containing alloys, enrichment is more significant for amorphous alloys, contributing to the better corrosion resistance of amorphous alloys. **Table 1** shows the concentrations of  $\text{Cr}^{3+}$  ions in the passive films formed on chromium-containing

**Figure 2** Pitting potentials of sputter-deposited Al–Mo and Al–W alloys, as well as high purity aluminum, in a borate buffer solution containing  $0.1 \text{ mol dm}^{-3}$  NaCl.<sup>24</sup>

**Table 1** Cationic fractions of  $\text{Cr}^{3+}$  ions in passive films formed on amorphous chromium-containing alloys and stainless steels in  $1 \text{ mol dm}^{-3}$  HCl solution<sup>52</sup>

Alloys	Cationic fraction of $\text{Cr}^{3+}$ ions in passive films	Passivation process
<i>Amorphous alloys</i>		
Fe-10Cr-13P-7C	0.97	Spontaneous passivation
Fe-3Cr-2Mo-13P-7C	0.57	Anodic polarization
Co-10Cr-20P	0.95	Spontaneous passivation
Ni-10Cr-20P	0.87	Spontaneous passivation
<i>Ferritic stainless steels</i>		
Fe-30Cr-(2Mo)	0.75	Anodic polarization
Fe-19Cr-(2Mo)	0.58	Anodic polarization

amorphous and crystalline alloys in  $1 \text{ mol dm}^{-3}$  HCl solution.<sup>52</sup> Crystalline ferritic stainless steels are passivated by anodic polarization, and the cationic concentrations of chromium species in the passive films are 75 and 58 at.% for Fe-30 at.% Cr and Fe-19 at.% Cr, respectively. For amorphous alloys, enrichment of chromium in passive films is more significant, although the contents of chromium in the alloys are lower than those in the crystalline alloys. For the amorphous Fe-10Cr-13P-7C alloy, which shows spontaneous passivation in  $1 \text{ mol dm}^{-3}$  HCl solution, the cationic percentage of chromium is 97 at.% in the passive film and only 3 at.% of cations are  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions. The concentration of chromium in the passive film formed on amorphous Fe-3Cr-2Mo-13P-C alloy is comparable to that in the passive film formed on crystalline Cr-19Cr steel. Thus, remarkable enrichment of chromium in the passive film is possible for amorphous alloys even if the chromium content in the alloy is as low as a few atomic percent. Amorphous alloys are metastable and hence surface reactivity is high. High reactivity of alloy surface leads to rapid dissolution of unnecessary alloying constituents, assisting the fast and significant enrichment of chromium species to form a stable and highly protective passive film.

Amorphous alloys are not always corrosion-resistant. The presence of a corrosion-resistant element is essential for improved corrosion resistance. In the absence of a corrosion-resistant element, amorphization increases the reactivity of the metal surface,

**Figure 3** Anodic dissolution rate of amorphous Co-25B alloy at  $-0.3 \text{ V}$  versus SCE in a solution of pH 1.8 containing  $0.5 \text{ mol dm}^{-3}$   $\text{Na}_2\text{SO}_4$ . After heat treatment at several temperatures.<sup>54</sup>

resulting in the occurrence of more aggressive corrosion. For instance, active dissolution rates of amorphous Fe-Cr-P-C alloys are larger than those of crystalline alloys with similar composition.<sup>54</sup> During annealing of amorphous Co-25 at.% B alloy, the alloy crystallizes to a  $\text{Co}_3\text{B}$  phase. The  $\text{Co}_3\text{B}$  phase decomposes to  $\text{Co}_2\text{B}$  and Co by further annealing at higher temperatures. Figure 3 shows the anodic dissolution current density of the Co-25 at.% B alloy at  $-0.3 \text{ V}$  versus SCE in  $0.5 \text{ mol dm}^{-3}$   $\text{Na}_2\text{SO}_4$  (pH 1.8) after annealing at various temperatures.<sup>55</sup> The dissolution rate of the amorphous Co-25 at.% B alloy decreases due to crystallization to  $\text{Co}_3\text{B}$ , indicating higher reactivity of the amorphous surface than that of the crystalline counterpart. Increased dissolution rate again above 623 K is associated with the chemical heterogeneity produced by decomposition of  $\text{Co}_3\text{B}$  to  $\text{Co}_2\text{B}$  and Co.

Another important point for the improved corrosion resistance of amorphous alloys is linked to the fact that amorphous alloys are able to form supersaturated solid solutions containing one or more alloying elements. In amorphous alloys, corrosion-resistant elements can be added uniformly, exceeding the solubility limit at equilibrium. The solid solubility of an alloying element in aluminum is usually less than a few percent. Practical Al alloys consist of an fcc Al phase and an intermetallic compound phase, with concentration of alloying element in the fcc matrix phase remaining low. Thus, the pitting corrosion resistance is not highly enhanced by alloying. However, if the sputter deposition technique is applied for the preparation of aluminum alloys,

a single-phase aluminum alloy supersaturated with an alloying element can be produced in an almost entire composition range and amorphous structure is obtained in a wide composition range.<sup>28</sup> The pitting corrosion resistance of sputter-deposited Al–Mo and Al–W metastable solid solution alloys in a chloride-containing neutral solution increases significantly with an increase in alloying element content, as shown in Figure 2.<sup>22</sup> Corrosion rates of a range of sputter-deposited Al–early transition metal alloys in 1 mol dm<sup>−3</sup> HCl solution also greatly decreases with an increase in content of the alloying element.<sup>28</sup> The improved corrosion resistance of aluminum alloys supersaturated with an alloying element is attributed primarily to the formation of passive films containing corrosion-resistant elements.<sup>28,56–58</sup> Compositions of passive films formed by anodic polarization were examined by X-ray photoelectron spectroscopy (XPS). Based on the results of analysis, it has been proposed that MoO<sub>4</sub><sup>2−</sup>, CrOOH, Ta<sub>2</sub>O<sub>5</sub>, or ZrO<sub>2</sub> present in passive films inhibits the adsorption of chloride ions and increase resistance to pit initiation in chloride-containing neutral solutions.

However, there are also some reports that passive films on solid solution aluminum alloys, including Al–W alloys, are practically free from alloying element species,<sup>59–61</sup> although pitting potential greatly ennobles with increase in content of the alloying element. The improved corrosion resistance of aluminum alloys has also been discussed in terms of local dissolution kinetics; alloying improves pitting resistance through a reduction in the ability of pits to maintain the critical local environment necessary for growth.<sup>62</sup>

A systematic study has been undertaken using transmission electron microscopy and Rutherford backscattering spectroscopy (RBS) to elucidate the growth process of anodic films on single-phase aluminum alloys. During anodizing of most dilute aluminum alloys, only aluminum is oxidized initially at the alloy–film interface, forming an alumina film free from alloying element species.<sup>63</sup> The alloying element is accumulated in a thin alloy layer, ~1–2 nm thick, immediately beneath the anodic film. Once the average composition of the enriched alloy layer reaches a critical level, the alloying element is oxidized and incorporated into the oxide film, with the average composition of the enriched layer maintaining the critical level.<sup>64</sup> It has been proposed that in the enriched alloy layer, clusters of the alloying element or the alloying element-rich clusters are developed (Figure 4). The critical level of enrichment is dependent upon the alloying element. There is a good

**Figure 4** Schematic illustration showing development of tungsten clusters in the enriched alloy layer, ~2 nm thick, immediately beneath the anodic film, and subsequent oxidation of the cluster with a critical size on a dilute Al–W alloy.

correlation between the critical amount of alloying element in the enriched alloy layer and the Gibbs free energy per equivalent of the formation of alloying element oxide (Figure 5).<sup>63</sup> An element with larger Gibbs free energy per equivalent for formation of oxide, that is, a nobler element, has more significant enrichment. No enrichment of an alloying element occurs when the alloying element has a Gibbs free energy per equivalent for formation of oxide similar to or less than that of Al<sub>2</sub>O<sub>3</sub>. In addition to the growth of anodic films at high current efficiency, preferential oxidation of aluminum and accumulation of an alloying element at the alloy surface also occur during chemical etching of aluminum alloys in alkaline solutions, chemical polishing, and electropolishing.<sup>65,66</sup> In neutral chloride-containing solutions, the dissolution rate of the passive film on aluminum alloys is considerably low unless localized attack occurs. Thus passive films free from alloying element species have been detected by surface analysis. Dissolution of alloy results in accumulation of the alloying element at the alloy surface once local breakdown of passive film occurs. Thus, finally, the passive film containing corrosion-resistant alloying element species may be developed, probably inhibiting the growth of pits.

### 3.20.1.3 Role of Alloying Elements in Improving Corrosion Resistance

#### 3.20.1.3.1 Phosphorus

Amorphous alloys are classified as metal–metal and metal–metalloid alloy systems. Metalloid elements, such as boron, carbon, silicon, and phosphorus, are added primarily for enhancing glass-forming ability.

**Figure 5** The steady-state enrichment of the alloy predicted for anodizing of binary aluminum alloys, containing ~1–5 at.% alloying element. Predictions are obtained using the relationship between enrichment and Gibbs free energy per equivalent for formation of the alloying element oxide derived from experimental results for a limited range of alloys anodized at  $50 \text{ A m}^{-2}$  at 298 K.

Among such metalloid elements, phosphorus is particularly beneficial in enhancing corrosion resistance, although it is known that phosphorus segregates at the grain boundaries of stainless steels and induces intergranular corrosion and stress-corrosion cracking of stainless steels. Amorphous Fe–Cr–13Si–7B and Fe–Cr–20B alloys in  $9 \text{ mol dm}^{-3}$   $\text{H}_2\text{SO}_4$  solution dissolve actively and their corrosion rates increase with increasing chromium content. In contrast, the corrosion rates of amorphous Fe–Cr–13P–7C and Fe–Cr–13P–7B alloys in the same solution decrease markedly with the addition of more than 7 at.% chromium.<sup>67</sup> For Ni-based amorphous alloys, the addition of phosphorus reduces the corrosion rate in hydrochloric acid even if a passivating element is absent. The amorphous Ni–20P alloy shows a low corrosion rate of less than  $0.1 \text{ mm year}^{-1}$  even in concentrated HCl solution, in which nickel metal dissolves aggressively.<sup>68</sup> Marked decrease in the corrosion rate has been found with the addition of only small amounts of phosphorus to amorphous Ni–Ta alloys; the addition of 2 at.% phosphorus decreases the corrosion rate by more than four orders of magnitude in boiling  $6 \text{ mol dm}^{-3}$  HCl solution.<sup>7</sup>

The high corrosion resistance of amorphous Ni–P alloys in acid solutions is not associated with oxide-based passivity. The alloys do not reveal a clear

active–passive transition, and the anodic current density increases gradually with anodic potential.<sup>69–71</sup> The corrosion rate of the amorphous Ni–19P alloy is not dependent upon the concentration of HCl—unusual behavior for oxide-based passivity.<sup>72</sup> Chemical passivity by adsorption of hypophosphite ions was proposed on the basis of results of XPS analysis of Ni–P alloy specimens polarized anodically in deaerated HCl and  $\text{H}_2\text{SO}_4$  solutions.<sup>69</sup> In addition to hypophosphite ions, enrichment of elemental phosphorus as a consequence of preferential dissolution of nickel was found by XPS analysis. Kinetic analysis of anodic dissolution of the amorphous Ni–P alloy in HCl solution revealed that the dissolution current density follows Fick’s second law (Figure 6), thus being diffusion-controlled.<sup>73</sup> An explanation of these results is that the elemental phosphorus layer formed by selective dissolution of nickel acts as a diffusion barrier for dissolution of nickel, reducing the dissolution rate of the alloy. The elemental phosphorus layer has high cathodic activity for proton and oxygen reduction. Thus, the formation of an elemental phosphorus layer shifts the corrosion potential in the noble direction as a consequence of the enhancement of cathodic activity and suppression of anodic dissolution. When a passivating element, such as chromium, is present, ennoblement of the corrosion potential promotes

**Figure 6** Reciprocal of square of current density  $i$  for dissolution of nickel from a melt-spun amorphous Ni-19P alloy specimen at 100 mV versus SCE in 1 mol dm<sup>-3</sup> HCl at three different temperature as a function of time  $t$ .<sup>73</sup>

passivation. This may be the reason why many amorphous alloys containing a passivating element and phosphorus, including amorphous Ni-Cr-P and Fe-Cr-P-C alloys, are spontaneously passive even in concentrated acid solutions.

In these studies, the chemical state of phosphorus species has been analyzed by XPS. Special attention must be paid to the characterization of passive films by XPS. Exposure of the specimen surface to air during transfer of the specimen from the electrochemical cell to the spectrometer often changes the chemical state of species in passive films. For instance, surface elemental phosphorus changes to phosphate species.<sup>74</sup> The chemical state of molybdenum in passive films on molybdenum-containing corrosion-resistant alloys also changes from Mo<sup>4+</sup> to Mo<sup>6+</sup> species during exposure to air. For precise identification of the chemical species in passive films by XPS, exposure of specimens to air before introduction into the spectrometer must be avoided.

### 3.20.1.3.2 Synergy of corrosion-resistant elements

It is well known that the addition of molybdenum to stainless steels improves localized corrosion in chloride-containing solutions. Molybdenum also reduces active dissolution rates of stainless steels in acid solutions. Even for amorphous alloys, the addition of molybdenum markedly improves the corrosion resistance of chromium-containing amorphous alloys.<sup>5,75,76</sup> In the active dissolution potential region of chromium, molybdenum is passive, forming stable tetravalent molybdenum species. Such stable molybdenum species

**Figure 7** Structures of sputter-deposited Cr-valve metals alloys identified by X-ray diffraction.

reduce the active dissolution rates of stainless steels and chromium-containing amorphous alloys. In addition to active dissolution rates, the stability of the passivity of stainless steels and amorphous alloys is enhanced by the addition of molybdenum. Because molybdenum dissolves transpassively as molybdate ions in the passive potential region of the alloys, the composition of passive films on molybdenum-containing alloys is often not greatly different from that on molybdenum-free counterparts. There are several reports on the role of molybdenum in enhancing the stability of a passive state.<sup>4,77,78</sup> The precise role of molybdenum in enhancing passivity is still a subject of controversy.

Ideal corrosion-resistant materials should be alloys consisting only of corrosion-resistant elements. Such alloys have been prepared by a magnetron sputtering method, and, interestingly, it has been revealed that the alloys show superior corrosion resistance to that of each alloy-constituting metal. **Figure 7** shows structures of sputter-deposited chromium-valve metal alloys identified by X-ray diffraction.<sup>31-33</sup> The alloys show an amorphous single-phase structure in a wide composition range. Even crystalline alloys are single phase. Their corrosion rates in 6 mol dm<sup>-3</sup> HCl and 12 mol dm<sup>-3</sup> HCl solution are shown in **Figure 8**. In 6 mol dm<sup>-3</sup> HCl solution, chromium and titanium metals dissolve actively, but binary Cr-Ti alloys are spontaneously passive and show extremely low corrosion rates, several orders of magnitude lower than those of the alloy-constituting elements.<sup>33</sup> The binary amorphous Cr-Zr alloys also reveal low corrosion rates in the 6 mol dm<sup>-3</sup> HCl solution, the rates decreasing with increasing chromium content.<sup>32</sup> The binary amorphous Cr-Ta alloys are immune even in 12 mol dm<sup>-3</sup> HCl solution at 303 K in a wide composition range. Corrosion resistance of binary Cr-Nb alloys is also better than that of

**Figure 8** Corrosion rates of sputter-deposited (a) Cr-Ti and Cr-Zr alloys in 6 mol dm<sup>-3</sup> HCl solutions and (b) Cr-Nb and Cr-Ta alloys in 12 mol dm<sup>-3</sup> HCl solution at 303 K.<sup>31-33</sup>

chromium and niobium metals.<sup>31</sup> Again, corrosion rates decrease with increasing chromium content.

Such excellent corrosion resistance of amorphous Cr-valve metal alloys was interpreted from XPS analyses of passive films; passive films consisting of double oxyhydroxides containing chromium and valve metal cations are remarkably protective in concentrated hydrochloric acids.<sup>45-48</sup> The formation of uniform double oxyhydroxides was identified from the shift of peak binding energies of photoelectrons of each cation. Similarly, Mo-valve metal alloys and W-valve metal alloys prepared by magnetron sputtering reveal high corrosion resistance in concentrated HCl solution. Their corrosion resistance is better than that of the corresponding alloy-constituting metals.<sup>36-40,42,79</sup>

#### 3.20.1.4 Corrosion Behavior of Bulk Metallic Glasses

The discovery in the late 1980s of amorphous alloys with extremely high glass-forming ability has eliminated the shape limitation of amorphous alloys, and a wide variety of applications are now being considered. As described in the review paper by Inoue,<sup>80</sup> a range of bulk metallic glasses, including Zr-based, Ti-based, Fe-based, Ni-based, Mg-based, and Ln-based alloys, have so far been developed by conventional casting and water cooling processes. The high glass-forming ability of these bulk metallic glasses is

associated with the stabilization of supercooled liquids. In metallic alloys, diffusion rates of alloy-constituting elements in their liquid phase are generally very fast at high temperatures just below the melting point. Due to high diffusivity, phase transformation occurs from supercooled liquid to a crystalline phase within a very short time of less than 10<sup>-5</sup> s. In multicomponent alloy systems forming bulk metallic glasses, diffusivity is suppressed, stabilizing the supercooled liquid state. Bulk metallic glasses are therefore obtained even with a slow cooling rate of 1 K s<sup>-1</sup> from liquids. Such metallic glasses with high glass-forming ability reveal in reality a wide temperature range of supercooled liquid region below the crystallization temperature.

Since bulk metallic glasses possess superior mechanical and physical properties, they have potential engineering importance. Thus, the corrosion behavior of bulk metallic glasses in potential service environments needs to be elucidated. Tailoring of extremely corrosion-resistant bulk metallic glasses may allow us to use metallic materials in aggressive environments, in which crystalline metallic materials cannot be used because of corrosion.

##### 3.20.1.4.1 Zr-based bulk metallic glasses

Zr-based bulk metallic glasses have been the most extensively studied glassy alloys. Because of their excellent mechanical properties of high tensile

strength, low Young's modulus, and large elastic elongation limit, Zr–Al–Cu–Ni bulk metallic glasses have been commercialized as golf clubs and pressure sensors. Good corrosion resistance of Zr–Al–Cu–Ni alloys was reported in chloride-free solutions in a wide pH range.<sup>81,82</sup> Their corrosion behavior is similar to that of zirconium metal. Zirconium is one of the valve metals, showing spontaneous passivation and high corrosion resistance in chloride-free acid, neutral, and alkaline solutions.<sup>83</sup> The passive film formed on Zr–Al–Cu–Ni alloys consists mainly of zirconium oxide with a small fraction of aluminum cation. For the Zr–Ti–Nb–Cu–Ni–Al alloy, it was revealed that in 0.5 mol dm<sup>-3</sup> H<sub>2</sub>SO<sub>4</sub> and 1 mol dm<sup>-3</sup> HNO<sub>3</sub> solutions, the fully amorphous alloy showed better passivation stability than nanocrystalline, quasi-crystalline, and crystalline ones with the same composition.<sup>84</sup>

In contrast to their high corrosion resistance in chloride-free solutions, Zr-based metallic glasses suffer pitting corrosion in chloride-containing solutions. The pitting occurs because of the existence of micrometer-sized crystalline inclusions.<sup>82</sup> Inclusions develop during casting at a slow cooling rate, being induced by oxygen in the casting atmosphere; bulk Zr–Al–Cu–Ni alloys containing higher oxygen content develop large fractions of crystalline inclusions.<sup>81</sup> The shape and size of the crystalline inclusions as well as their concentration are largely dependent upon the alloy composition, oxygen content, and cooling rate. The pitting is initiated preferentially at the interface between the amorphous matrix and a crystalline inclusion.

In addition to the reduced fraction of crystalline inclusions, modification of alloy composition is effective in improving pitting corrosion resistance. The addition of 5 at.% of titanium or niobium to Zr–30Cu–10Al–5Ni bulk metallic glass greatly reduces the pitting susceptibility in 0.05 mol dm<sup>-3</sup> NaCl solution.<sup>85</sup> The pitting corrosion resistance of melt-spun Zr–20Cu–10Al–10Ni alloy is enhanced by substituting zirconium with niobium up to 20 at.%.<sup>86</sup> The corrosion rate of the Zr-based alloy in 1 mol dm<sup>-3</sup> HCl solution decreases significantly with increasing niobium content. In 3% NaCl solution, the addition of niobium greatly shifts the pitting potential of the alloy in the positive direction.

Zr-based bulk metallic glasses have also attracted attention as biomaterials because of suitable mechanical properties as well as biocompatibility.<sup>87</sup> The bulk metallic glass of Zr–17.9Cu–14.6Ni–10Al–5Ti, commonly known as Vitreloy 105, possesses a low modulus

that is close to that of bone, as well as high elastic limit and superior strength. An unusual collection of mechanical properties of the bulk metallic glass would be advantageous in various biomedical applications.

As a part of investigations of the biocompatibility of Zr-based bulk metallic glasses, their corrosion behavior has been examined in artificial body fluids.<sup>87–90</sup> It has been found that pitting corrosion occurs on Zr-based metallic glasses in phosphate-buffered saline environments by anodic polarization. However, the susceptibility of pitting is not so high, particularly at low chloride concentrations. The corrosion behavior of the Vitreloy 105 bulk metallic glass has been compared with that of common biomaterials of 316L stainless steel, Ti–6Al–4V, and CoCrMo alloys in a phosphate-buffered saline solution.<sup>87</sup> The corrosion rate of the Zr-based bulk metallic glass was lower than that of 316L stainless steel, being comparable with the corrosion rates of Ti–6Al–4V and CoCrMo alloys. Furthermore, bulk metallic glass showed better localized corrosion resistance than 316L stainless steel. The combined mechanical and electrochemical properties of Zr-based bulk metallic glasses indicate their potential as a new generation of biomaterials.

#### 3.20.1.4.2 Corrosion-resistant bulk metallic glasses

It has been demonstrated that bulk forms of iron-based and nickel-based metallic glasses containing sufficient amounts of corrosion-resistant elements show excellent corrosion resistance in aggressive acid solutions. Corrosion-resistant rod-shaped Ni-based alloys, including Ni–5Cr–5Ta–3Mo–16P–4B, Ni–15Cr–10Mo–16P–4B, Ni–(10–15)Cr–5Ta–16P–4B and Ni–(40–*x*)Nb–*x*Ta–(3–5)P alloys, of 1–2 mm in diameter were successfully prepared by copper mold casting.<sup>51,91,92</sup> These alloys are spontaneously passive in 6 mol dm<sup>-3</sup> HCl solution, showing very low corrosion rates. The corrosion resistance of bulk metallic glasses is comparable to that of metal-spun thin ribbons of the same composition. Thus, the cooling rate does not influence the corrosion behavior of metallic glasses. To obtain sufficient glass-forming ability to form bulk metallic glasses, large amounts of corrosion-resistant elements cannot be added to alloys. However, the combined addition of two or three corrosion-resistant elements to nickel-based and iron-based alloys provides excellent corrosion resistance. The combination of chromium, tantalum, and molybdenum is effective for enhancing corrosion resistance.<sup>50,92</sup>

A bulk form of corrosion-resistant metallic glasses was also successfully prepared by sheath-rolling consolidation of encased amorphous alloy powders. The Ni–10Cr–5Nb–16P–4B metallic glass shows a wide temperature range of supercooled liquid region (more than 50 K) below crystallization. Alloy powders prepared by a gas atomization technique were encased in a stainless steel tube and then heated to temperature of the supercooled liquid region. Sheath-rolling at this temperature produced a bulk metallic glass plate. The potential application of the sheath-rolled and copper-mold cast Ni–10Cr–5Nb–16P–4B bulk metallic glass in an exhaust gas chimney of a waste incinerator has been pointed out.<sup>93</sup> In the environment at 423 K and 463 K, severe corrosion attack occurred on type-316L stainless steel and Alloy B due to dew-point corrosion, whereas bulk metallic glass retained its metallic luster and showed no detectable corrosion weight change for 20 days. Superior corrosion resistance of iron-based bulk metallic glasses containing chromium and molybdenum has also been reported. The availability of corrosion-resistant bulk metallic glasses opens up their applications to very aggressive environments, in which conventional crystalline metallic materials cannot be used due to severe corrosion.

### 3.20.1.5 Corrosion Behavior of Nanocrystalline Alloys

#### 3.20.1.5.1 Nanocrystalline-precipitated amorphous alloys

It is likely that precipitation of crystalline phases in an amorphous alloy matrix containing corrosion-resistant elements is detrimental to its corrosion resistance because of the increased chemical heterogeneity. It is known that amorphous alloys containing corrosion-resistant elements show higher corrosion resistance than fully crystallized alloys with the same composition. This is, however, not always true when nanocrystalline phases are precipitated in an amorphous matrix phase. In certain amorphous Al alloys and Zr alloys,<sup>94–99</sup> it has been demonstrated that good resistance of fully amorphous alloys to localized pitting corrosion is not deteriorated or improved by nanocrystalline precipitation. Nanocrystalline precipitates can be introduced in an amorphous phase by heat treatment of fully amorphous alloys or by utilizing a slow cooling rate during the fabrication of amorphous alloys from the liquid state. The latter condition is required to develop bulk metallic glasses such that they often contain

nanocrystalline precipitates in an amorphous matrix. Thus an understanding of the influence of nanocrystalline precipitates on corrosion behavior is a crucial issue for the practical application of bulk metallic glasses. Furthermore, nanocrystalline-amorphous alloys have attracted attention since they show improved mechanical strength.<sup>100</sup> The crystallization behavior of amorphous alloys is dependent upon alloy composition. For aluminum-rich amorphous alloys, including Al–5Fe–5Gd, Al–8.7Ni–4.3Y, and Al–3Co–7Ce alloys, solute-lean fcc-Al phase nanocrystals are primarily precipitated in an amorphous matrix during heat treatment. Such amorphous–nanocrystalline alloys maintain high pitting potential in chloride-containing solutions comparable to that of fully amorphous alloys, though fully crystallized alloys show considerably low pitting potential.<sup>95–99</sup> For the Al–5Fe–5Gd alloy, even ennobled pitting potential in 0.6 mol dm<sup>−3</sup> NaCl solution by precipitation of 10–15 nm sized nanocrystals has been reported (Figure 9).<sup>98</sup> Ennoblement of pitting potential is also observed for amorphous Zr–Cr alloys; precipitation of hcp Zr nanocrystals of less than 20 nm shifts the pitting potential in the positive direction in 6 mol dm<sup>−3</sup> HCl solution.<sup>94</sup> Ennoblement of the pitting potential is explained by the enrichment of the solute in the amorphous matrix. Precipitation of nanocrystalline Zr induces enrichment of chromium in the amorphous phase, making the matrix phase more pitting-resistant. The presence of a critical size of nanocrystals, that is, 20 nm, in improving localized corrosion resistance has also been pointed out. Below the critical size, a chromium-enriched highly

**Figure 9** Pitting and repassivation potentials for Al–5Fe–5Gd in deaerated 0.6 mol dm<sup>−3</sup> NaCl. Pitting and repassivation potentials of pure Al are shown for comparison. Scan rate 0.1 mV s<sup>−1</sup>.<sup>98</sup>

protective passive film can cover the entire alloy surface, but preferential dissolution of a less corrosion-resistant phase occurs when the size of the precipitates exceeds the critical size.

There are also examples of precipitation of nanocrystals less than 10 nm size in amorphous matrix being detrimental in terms of corrosion. The copper-mold cast Ni-10Cr-5Ta-16P-4B bulk metallic glass contains an fcc nickel phase of 2–3 nm in size in the amorphous matrix, showing higher anodic dissolution current than that of fully amorphous alloy ribbon in potentiodynamic polarization curves.<sup>91</sup> Smaller sizes of the fcc Ni precipitates have lower detrimental effect. Sputter-deposited Cr-Nb alloys are spontaneously passive in 6 and 12 mol dm<sup>-3</sup> HCl solutions. The as-deposited alloys crystallize to a two-phase mixture of bcc Cr and Cr<sub>2</sub>Nb, Cr<sub>2</sub>Nb and niobium-rich amorphous phase, Cr<sub>2</sub>Nb and bcc Nb, or chromium-rich amorphous phase and bcc Nb, depending upon alloy composition and heat treatment conditions. The Cr<sub>2</sub>Nb phase has high corrosion resistance, similar to that of the amorphous single phase alloy. The formation of nanocrystalline bcc Cr and bcc Nb phases increases initial passive current density. However, the steady state passive current density is as low as that of the as-deposited alloy, as the amorphous or Cr<sub>2</sub>Nb matrix phase maintains high corrosion resistance. Thus, the formation of soluble nanocrystals in corrosion-resistant matrix phases increases the initial dissolution rate but not always the steady-state anodic dissolution rate.

### 3.20.1.5.2 Nanocrystallization of conventional crystalline corrosion-resistant materials

Finally, it may be worth mentioning that nanocrystallization of conventional corrosion-resistant materials such as stainless steel, markedly improves the susceptibility for localized corrosion without changing the alloy composition. Using a conventional type-304 stainless steel target, nanocrystalline stainless steel films have been prepared by sputter deposition.<sup>101,102</sup> The pitting potential of nanocrystalline films with grain size of 25 nm is ~850 mV more positive than that of conventional bulk material of the same composition, even though enrichment of chromium in the air-formed oxide is lower for nanocrystalline films.<sup>101</sup> Sputter-deposited films have a bcc structure. Improved pitting corrosion resistance may not be related to structural transformation from the fcc phase of bulk material to the bcc phase of nanocrystalline films, because the pitting potential of ferritic bulk stainless

steel containing 18% Cr is even lower than that of austenitic stainless steel with the same Cr content.

It is well accepted that pitting corrosion of stainless steel in chloride-containing environments is usually initiated at manganese sulfide particles in the steel. A recent study also suggests the possibility that pitting is triggered by an attack on chromium-depleted zones around the manganese sulfide particles.<sup>103</sup> In stainless steel films prepared by sputter deposition that produces single-phase materials dissolving most alloying and impurity elements, the chemical heterogeneity of the steel surface should be neglected. By using a process that forms nanograined metastable materials with reduced chemical heterogeneity, corrosion resistance can be improved remarkably without changing chemical compositions, even if there is a high concentration of impurity elements that are generally detrimental to corrosion.<sup>102</sup>

## Glossary

**Noble metal** A metal generally characterized by having relatively positive potentials and low corrosion rates when immersed in an aqueous environment by virtue of its relative thermodynamic stability with respect to its simple hydrated ions in solution (and not solely by its passivity).

**PGMs** The platinum group of metals that comprises: platinum, palladium, rhodium, ruthenium, osmium and iridium; or (PGM) a single element of that group.

**Sterling silver** An alloy containing at least 92.5% silver plus other (unspecified) alloying additions, commonly copper. In the United Kingdom, this level of purity is the minimum standard guaranteed by hallmark.

**Troy ounce** A historic unit of measurement common in medieval Europe and said to derive from the city of Troyes, France; approximately equal to 31.1 g. Currently used in the weighing, trading, and description of precious metals and jewels.

### 3.21.1 Introduction

The group of noble metals comprises adjacent elements from the second and third row of the transition metals and from groups 8b (platinum group metals – PGMs) and 1b (silver and gold) of the periodic table. They are characterized by their exceptional resistance to corrosive attack by a wide range of liquid and gaseous substances and their relative stability at high temperatures, conditions under which base metals would be rapidly oxidized. This resistance to chemical and oxidative attack arises principally from the inherent, high thermodynamic stability of the noble metals. Apart from gold (which does not form an oxide in aqueous media), in other noble metals a thin film of adsorbed oxygen or oxide may form under oxidizing or anodic conditions, which can enhance their corrosion resistance via passivity. In some materials, for example silver in halide solutions, salt films can accomplish a similar passivation effect.

Their high initial cost, combined with a mechanical strength which is generally inferior to that of the base metals, results in only a limited number of corrosion-related applications for the noble metals, and they are as used only as sheaths, linings, or coatings, for example,

electrodeposits. However, noble metals have some critical applications, for example, equipment for fine chemical and pharmaceutical production, for fiber drawing, in the glass industry, and for crystal growth.

Silver is produced in a number of countries, generally as a by-product from mining other materials, particularly lead, zinc, copper, nickel, and gold, although some significant primary mines operate in Australia, Mexico, and Russia. (Basic information regarding physical and mechanical properties, application, and production of the noble metals were obtained from the references listed.) The largest producers are in Latin America (e.g., Peru, Mexico, Chile), while China, Australia, and Eastern Europe also produce significant quantities. Gold is mined as a primary product in a number of countries (e.g., South Africa, Australia, Ghana), but is also produced as a secondary product from other mining operations (e.g., Peru, Indonesia). By far, the majority (>80%) of the PGMs are produced from primary resources in South Africa and Russia, with lesser amounts from secondary resources. [Table 1](#) shows estimated supply and demand figures for all the noble metals. Note the relatively small volumes of material recovered. In years of excess of supply over demand, stocks are built-up, which are then released when demand exceeds supply. This is demonstrated for ruthenium demand in 2006. Noble metals are subject to large fluctuations in price according to market demands.

### 3.21.2 Properties

Although in the majority of their applications the choice of noble metals is determined by their chemical property rather than by their physical and mechanical properties, some consideration of the latter is necessary. Therefore, important physical and mechanical properties are reported in [Tables 2 and 3](#).

#### 3.21.2.1 Silver and Gold

Silver in the fully annealed state is a soft, ductile metal, which is easily fabricated into the very wide range of forms employed in industry by the normal metal-working techniques such as drawing, spinning, rolling, etc. Silver work-hardens appreciably during fabrication. The mechanical strength of silver is markedly affected by an increase in temperature and falls to about 25% of the initial value of cold, hard-worked silver when the metal is heated to just over 200 °C. Silver has the highest electrical and thermal conductivities of all

**Table 1** Estimated supply/demand and average prices for noble metals in 2006

<i>Metal</i>	<i>Supply (tons)</i>	<i>Demand (tons)</i>	<i>Volume (m<sup>3</sup>)</i>	<i>Average Price (\$/oz: \$/kg)</i>	<i>\$/kg</i>
Silver	26 900	–	2569	11.5	370
Gold	3 400	–	176	635	20 450

the metals, and these properties are sometimes utilized for specialist applications. Silver is available in several grades, including fine silver, the normal commercial product containing a minimum of 99.95% silver, and

chemically pure silver containing a minimum of 99.99% silver, used for catalytic and special purposes where the presence of certain trace impurities may adversely affect its resistance to corrosion.

Silver is available in many standard forms – sheet, strip, foil of thicknesses down to 0.013 mm, rod, wire down to 0.013 mm diameter, gauze, tubes, bimetal as silver-clad copper or phosphor-bronze, and many others. It is easily fabricated by the normal techniques of rolling, spinning, drawing, etc., and readily binds to itself by fusion-welding using argon-arc welding. Flame welding may be used, but the resulting welds are often not as satisfactory, owing to the possibility of oxygen absorption while the metal is molten, followed by embrittlement by hydrogen. Fine silver filler rods may be used, and hammering the weld fillet down to the contour of the surrounding metal produces a very strong joint.

Gold is an extremely soft and ductile metal and exhibits little work hardening during deformation. Applications of gold are almost entirely restricted to thin linings or electrodeposits on base-metal equipment. It is available for industrial purposes in a grade containing a minimum of 99.9% gold in a wide range of forms – sheet, foil, tube, wire, etc. It is easily fabricated, and when it is being joined to itself, it may be fusion-welded with an oxy-hydrogen flame or hammer-welded at temperatures well below the melting point.

### 3.21.2.2 Platinum Group Metals

Pure platinum is soft, ductile, and easily fabricated, although its mechanical properties are affected by the degree of cold working and the presence of impurities or alloying constituents. In its applications, it is frequently alloyed with other PGMs; the melting points of its alloys with Rh, Ir, Os, and Ru being higher than the parent metal, those with Pd being lower. In most cases, the strength, rigidity, hardness, and resistance to corrosion are improved by alloying. Contamination with certain base metals (e.g., iron), however, can lead to embrittlement and failure of platinum and its alloys and, for example, if steel tongs are used to handle platinum at high temperatures, then they should be platinum-tipped to avoid iron pick-up.

The PGMs have a range of often unique properties that find critical use in a number of key applications, for example, in automotive catalysts, chemical catalysts, electronics, and jewelry; however, such applications are outside the scope of this chapter. Apart from palladium, the other PGMs are seldom used in isolation for corrosion-resistant applications, mainly because of their cost and availability. Palladium has very similar properties to platinum but is less corrosion resistant. Its remarkable ability to absorb large quantities of hydrogen is used in hydrogen permeation

membranes and in similar applications such as solid-state hydrogen reference electrodes. Iridium and osmium are characterized by their extreme densities, their high melting points, and their low ductility and high hardness, which are sometimes utilized in specialist corrosion and wear-resistant applications for hard alloys: for example, the traditional use of iridium–osmium tipped fountain pens and precision pivots and bearings. Rhodium, ruthenium, and iridium are used as alloying additions to platinum in order to improve the mechanical and physical properties. Iridium is used in specialist equipment for fine crystal growth (e.g., in electronics), especially from 1600 to 1900 °C. Both iridium and osmium form oxides that are volatile at modest temperatures, which, in the case of osmium, forms and volatilizes at room temperature.

Platinum is available as sheet, foil down to 0.0064 mm thick, tube, rod, wire down to 0.0064 mm diameter, wire down to 0.001 mm diameter, and clad on thin sections of base metals, for example, copper, nickel, Inconel, etc. Platinum, palladium, and the normal alloys of platinum used in industry are easily workable by the normal techniques of spinning, drawing, rolling, etc. To present a chemically clean surface of platinum and its alloys after fabrication, they may be pickled in hot concentrated hydrochloric acid to remove traces of iron and other contaminants; this is important for certain catalytic and high temperature applications. In rolling or drawing thin sections of platinum, care must be taken to ensure that no dirt or other particles are worked into the metal, as these may later be chemically or electrolytically removed, leaving defects in the platinum.

When platinum or its alloys are joined, properties of the weld or solder must be such that it is no less corrosion- or oxidation-resistant for the application in question than the parent metal. Platinum and its alloys are readily joined to themselves and to certain base metals, for example, iron, nickel, and copper. The principal methods for joining platinum are as follows

1. Fusion welding, using a platinum or alloy filler rod of the same composition as the parent metal and a shielded electric arc or an oxy-hydrogen flame (an oxy-acetylene flame may cause carbon pick-up by the molten metal). The weld fillets are then cold hammered to the contours of the surrounding metal to provide a strong joint.
2. Platinum and rhodium–platinum alloys when cleaned are readily hammer-welded to themselves and to each other at temperatures in the range 800–1000 °C. The welds so produced are completely homogeneous.

3. Fine gold, copper, silver–palladium, or platinum–palladium–gold–copper alloys may be used to solder platinum to itself and to its alloys, or to steels, nickel, etc. No fluxes are used, and soft solders should not be employed.

#### 3.21.2.2.1 Platinum–rhodium

Rhodium alloys readily with platinum in all proportions, although the workability of the resulting alloy decreases rapidly with increasing rhodium content. Alloys containing up to about 40% rhodium, however, are workable and find numerous applications. Alloys that contain more than 40% rhodium, while very difficult to fabricate, are almost immune from attack by oxidizing acids. The Pt–10Rh alloy is particularly resistant to attack by free wet chlorine such as that produced by the combustion of halogenated organic vapors.

The resistance of rhodium–platinum alloys to corrosion is about the same as, or slightly better than, that of pure platinum, but they are much more stable at high temperatures. They have excellent resistance to creep above 1000 °C, a factor which largely determines their extensive use in the glass industry, where continuous temperatures sometimes exceeding 1500 °C are encountered. Rhodium additions to platinum reduce appreciably the volatilization of pure platinum at high temperatures.

#### 3.21.2.2.2 Alloys of platinum with other PGMs

Iridium alloys with platinum in all proportions and alloys containing up to about 40% iridium are workable, although considerably harder than pure platinum. The creep resistance of iridium–platinum alloys is better than that of rhodium–platinum alloys at temperatures below 500 °C. Their stability at high temperatures, however, is lower, owing to the higher rate of formation of a volatile iridium oxide. Additions of ruthenium increase the hardness of platinum substantially, but the limit of workability is reached at about 15% ruthenium. Apart from a somewhat greater tendency to oxide formation at temperatures above 800 °C, the resistance to corrosion of ruthenium–platinum alloys is comparable with that of iridium–platinum alloys of similar composition.

#### 3.21.2.2.3 Dispersion strengthened alloys

Platinum–rhodium alloys are used extensively in high temperature applications for crucibles and related equipment, especially in the glass industry. The increasing cost of rhodium and platinum provides a strong driver to reduce overall costs, and this

has led to the development of a range of oxide dispersion strengthened alloys and composite alloys using, for example, platinum coatings on palladium cores.<sup>1</sup> The most common formulation is of zirconia-dispersed Pt–10Rh alloy<sup>2</sup> with somewhat higher room temperature strength than Pt–10Rh and 2–3 times the creep rupture properties of Pt–40Rh at 1400 °C (Table 3).

### 3.21.3 Thermodynamic Behavior

The behavior of the noble metals (indeed all metals) in different environments is determined by three principal factors:

1. their relative thermodynamic stability (nobility);
2. the formation of passive protective films;
3. their tendency to form complex ions in solution.

In the absence of species that form soluble complex ions, the noble metals are extremely resistant to corrosion by aqueous solutions of alkalis, salts, and acids. However, the resistance of silver to oxidizing acids is generally lower than that of the other noble metals, while in halogen acids, it forms a protective film of insoluble halide. Silver also differs from the other noble metals in forming a sulfide tarnish film in the presence of reduced sulfur compounds. Where complexing species are present and they stabilize the metal ions in solution (e.g., cyanide) the noble metals will corrode.

#### 3.21.3.1 Silver

Silver, with a standard electrode potential  $E_{\text{Ag}^+/\text{Ag}} = 0.79 \text{ V}$ , is exceeded in nobility only by gold and the PGMs. The Pourbaix diagram for silver (Figure 1) shows that at potentials below about 0.4 V and in the absence of complexing ions, silver is immune to attack over almost the whole pH range.

The situation is different in the presence of complexing agents, such as cyanide, or with species with which silver forms an insoluble salt, such as chloride. Thus, the presence of halides (with the exception of fluoride) substantially increases the zone of passivity, because of the formation of halide salt films as passivation layers;<sup>1</sup> at 25 °C, the solubility product of AgCl is  $1.7 \times 10^{-10}$ , of AgBr is  $5.0 \times 10^{-13}$ , and AgI is  $8.5 \times 10^{-17}$ ; AgF is soluble. Silver will also passivate in solutions containing sulfate. However, in the presence of sulfide, silver can form Ag<sub>2</sub>S tarnish films, even in the absence of air.

Silver, therefore, is thermodynamically stable in reducing acids, for example, hydrochloric acid, acetic

**Figure 1** Pourbaix ( $E$ -pH) diagram for silver at a metal ion concentration of  $10^{-5}$  M. Reproduced from *HSC 6.1: Thermochemical Database*; Outotec, 2007.

acid, phosphoric acid, provided oxidizing substances are absent. Oxidizing acids, for example, nitric acid, hot sulfuric acid at concentrations exceeding 80%, and reducing acids containing oxidizing agents will be corrosive to silver, and the diagram shows that an extensive zone of corrosion occurs at elevated potentials in the acid region. When silver is passivated by a halide film, as is formed for example in hydrochloric acid, the film is tenacious, self-healing, and highly insoluble. However, such films are easily reduced, for example, by galvanic coupling to a less noble metal such as zinc, aluminum, and passive stainless steels and nickel-based alloys. In such instances, silver will continuously corrode. In highly alkaline solution, silver corrodes only within a narrow region of potential, provided complexants and oxidants are absent. It is thus suitable to handle aqueous solutions of sodium or potassium hydroxides at all concentrations; it is also unaffected by fused alkalis.

### 3.21.3.2 Gold

The high resistance of gold to attack by a very wide range of corrosive media results from its exceptional thermodynamic stability in aqueous conditions. The Pourbaix diagram for gold (Figure 2) shows immunity from attack over the whole range of pH values and, uniquely, gold's zone of thermodynamic stability

includes the entire region of water stability; thus, it is immune from corrosion in aerated water. Gold, however, is easily complexed, and its solubility in hydrochloric acid containing an oxidizing agent (e.g., nitric acid) results from a combination of high redox potential and the formation of chloroaurate complex ions ( $\text{AuCl}_4^-$ ). The unstable  $\text{Au}^+$  ion and the easily reducible  $\text{Au}^{3+}$  ion also readily form stable complexes. Gold is unaffected in alkaline solutions, but in the presence of cyanides the soluble  $\text{Au}(\text{CN})_2^-$  ion is readily formed by air oxidation. This reaction forms the basis for the extraction of gold from its ores on an industrial scale.

### 3.21.3.3 Platinum Group Metals

All the six PGMs are highly resistant to corrosion by most acids, alkalis, and other chemicals. As may be seen from the potential-pH diagram (Figure 3), platinum is immune to attack at almost all pH levels, although it will corrode slowly in aqua regia (concentrated hydrochloric acid + nitric acid). It should also be noted that platinum is significantly less noble than gold and is covered by an oxide film in air (unlike gold, which is oxide free).

Platinum is unaffected by most organic compounds, although some compounds may catalytically decompose or become oxidized on a platinum surface at

**Figure 2** Pourbaix diagram for gold at a metal ion concentration of  $10^{-5}$  M. Reproduced from *HSC 6.1: Thermochemical Database*; Outotec, 2007.

**Figure 3** Pourbaix diagram for platinum at a metal ion concentration of  $10^{-5}$  M. Reproduced from *HSC 6.1: Thermochemical Database*; Outotec, 2007.

elevated temperatures, resulting in an etched appearance of the metal.

Compared with platinum, palladium is significantly less noble, as can be seen from its Pourbaix diagram (Figure 4), where an extended passive oxide region is notable (PdO) and simple  $\text{Pd}^{2+}$  aquo-ions are stable at low pH and high potential (compare with platinum). However, palladium is relatively stable in the presence

of aqueous solutions of all pH values with the exception of strong oxidizing agents and complexing substances. Nonoxidizing acids, for example, acetic, oxalic, hydrofluoric, and sulfuric acids, have no effect on the metal at ordinary temperatures. Strongly oxidizing acids, however, for example, hydrochloric acid containing nitric acid, rapidly attack palladium. Dilute nitric acid attacks palladium only slowly, but the metal

**Figure 4** Pourbaix diagram for palladium at a metal ion concentration of  $10^{-5}$  M. Reproduced from *HSC 6.1: Thermochemical Database*; Outotec, 2007.

is rapidly corroded by the concentrated acid. Alloys of palladium with platinum, however, retain most of the corrosion resistance of platinum. In ordinary atmospheres, palladium is resistant to tarnish, but some discoloration due to sulfide-film formation may take place in industrial atmospheres containing sulfur dioxide. Alkaline solutions, even in the presence of oxidizing agents, are without significant effect.

The resistance of rhodium and iridium to chemical attack is very similar to that of platinum, although with a wider domain of stability, particularly, at low pH in oxidizing solution. Additions of rhodium or iridium to platinum generally raise the overall corrosion resistance of the alloy to a very wide range of reagents. Like the other noble metals, in the absence of complexing agents both rhodium and iridium are stable in aqueous solutions at all pH values. Both metals are unattacked by alkalis, acids or oxidizing agents in aqueous solution, although oxidizing molten salts (e.g., potassium nitrate) are more corrosive. Iridium, in particular, has excellent resistance to fused lead oxide, silicates, and molten copper and iron at temperatures up to 1500 °C.

Ruthenium and osmium are decidedly less noble than the other four elements in the platinum group. Both exist in numerous valency states and very readily form complexes. Ruthenium is not attacked by water or noncomplexing acids, but is easily corroded by oxidizing alkaline solutions, such as peroxides and

alkaline hypochlorites. Osmium forms a volatile (and toxic) oxide at room temperature in air, and hence, should be handled with care.

### 3.21.4 Corrosion and Electrochemistry

There is great interest in the electrochemistry of the noble metals; many of them having scientifically interesting and sometimes unique properties that can result in commercially useful attributes, for example, in electrocatalysis. However, it is impossible to provide a fully comprehensive review in this section and it is not even attempted. Thus, the general electrochemistry of the materials is only superficially considered here. From the perspective of corrosion, one of the most interesting and potentially valuable effects is the substantial reduction in the corrosion rate of passive alloys (i.e., stainless steels) as a consequence of the addition of small amounts of noble metal. For further detailed information the reader is referred to the separate chapter on cathodic modification of stainless steels and titanium.

#### 3.21.4.1 Silver

##### 3.21.4.1.1 Anodic processes

Silver generally corrodes anodically below the reversible oxygen potential, unless an insoluble

oxide or salt is formed. When silver is used as an anode in sulfuric acid solutions, its behavior shows an analogy with that of lead. Silver sulfate,  $\text{Ag}_2\text{SO}_4$ , is first formed, and this acts as a passive film.<sup>3</sup> When the potential is raised the sulfate is oxidized to  $\text{AgO}$ , which may be cathodically reduced back to  $\text{Ag}_2\text{SO}_4$  at a potential lower than that required for its initial formation. When made anodic in nitrate solutions, silver generally dissolves quantitatively as  $\text{Ag}^+$ , and this forms the basis of the electrorefining techniques widely used in the industry. Similar considerations apply to the anodic behavior of silver in cyanide solutions, where silver forms a cyanide complex. In chloride solutions, silver anodes become covered with a layer of silver chloride.<sup>4</sup> The anodic oxidation and reduction of silver in alkaline solutions is of interest in battery applications, and a few percent of alloying additions of palladium or gold improve the capacity of silver oxide electrodes.<sup>5</sup>

Silver is not generally resistant to sulfidizing environments, as is commonly demonstrated by the atmospheric tarnishing of silver (see below), generally the formation of a sulfide film of varying thickness. The aqueous corrosion of silver in sulfide solution was studied using electrochemical and analytical methods in order to elucidate the mechanisms.<sup>6</sup> Under anodic polarization, silver initially forms  $\text{Ag}_2\text{S}$ , which is then further oxidized to  $\text{Ag}_2\text{O}$  at higher potentials. The limiting anodic current density was found to be proportional to the sulfide concentration in solution, and this was thought to be due to diffusion of  $\text{SH}^-$  ion to the silver surface. The reaction rate increased as the pH increased, which is consistent with the change in speciation of  $\text{SH}^-$  ion in solution; little effect on corrosion rate was found with dissolved oxygen content. X-ray diffraction and Raman spectroscopy indicated the formation of  $\text{Ag}_2\text{S}$  as the main reaction product.

#### 3.21.4.1.2 Atmospheric corrosion and tarnishing

Silver is traditionally used decoratively and functionally in fine cutlery and tableware and is valued for its high luster and long life. It has also been widely used in electrical contact applications because of its high conductivity. Although silver is stable to oxidation, it forms a tarnish film in atmospheres containing inorganic or organic sulfur species and chlorides. This dulls the surface and detracts from appearance; the film also increases contact resistances. Atmospheric levels below 0.1 ppm of  $\text{H}_2\text{S}$ ,  $\text{SO}_2$ , and  $\text{HCl}$  are sufficient to tarnish silver at measurable growth rates. Dry nitrogen atmospheres stops tarnish film growth, which

suggests that the process is electrochemical and occurs in a thin adsorbed water layer on the metal surface and requires air as oxidant.<sup>7</sup> Long chain organic molecules containing sulfur were also found to strongly interact with silver surfaces, giving tarnish films of similar composition to those found in  $\text{H}_2\text{S}$ .<sup>8</sup>

The sulfidation of silver was studied in a tubular reactor, with well-controlled mass transfer characteristics. In dry air,  $\text{H}_2\text{S}$  slowly reacted with silver at a constant rate, independent of the flow. The mechanism is surface controlled, and was found to involve atmospheric oxygen; the rate being increased significantly in the presence of an alternative oxidant ( $\text{NO}_x$ ). In humid air, corrosion was over 1000 times faster, with the kinetics now controlled by mass transfer of  $\text{H}_2\text{S}$  in the gas phase.<sup>9</sup> In a series of comprehensive studies, the effect of carbon oxysulfides ( $\text{COS}$ ) was also investigated and it was concluded that the sulfidation of silver by  $\text{COS}$  was at least as significant as by  $\text{H}_2\text{S}$ ; the detailed mechanisms of film growth were also determined.<sup>10</sup>

Significant research effort has been expended on preventing (or at least reducing) the kinetics of the tarnishing process. These apply one of three strategies: coating the silver, alloying the silver, or use of a tarnish (corrosion) inhibitor. In the electronics sector, electroplating with gold is commonly used in order to limit corrosion of contacts and consequent increase in contact resistance, and is generally a successful solution. However, if the excellent appearance of decorative silver is required, gold plating (i.e., a gilt finish) is not acceptable.

A number of treatments have been considered for tarnish protection, including palladium or rhodium plating (importantly the latter causes very little color change on silver), tarnish inhibitors incorporated into commercial polishes (commonly using organic thiols),<sup>11</sup> treatments with lacquers or plasma-polymerized coatings, and formation of self-assembled monolayers.<sup>12</sup> In a comparative evaluation of their performance, the commercial tarnish inhibitors were found not to provide significant protection, while the most effective treatment was an organic lacquer, followed by rhodium plating and the self-assembled monolayer treatment.<sup>13</sup>

The search for a tarnish-resistant silver alloy has been ongoing for at least 70 years with, until recently, comparatively little success. Although alloys of silver that substitute some of the copper content for palladium, nickel, zinc, or tin do tarnish more slowly than standard sterling silver,<sup>14</sup> they have no compelling advantage. Novel formulations for decorative silver alloys are constrained by the need to stay

within the purity level for hallmarked sterling silver (i.e., more than 92.5% silver content). Until recently, no novel alloy had significant proven advantages in this application. However, an alloy containing germanium has been shown to be relatively resistant to sulfide tarnishing, and is now marketed as 'Argentium'.<sup>15</sup> The improved surface properties are due to preferential oxidation of germanium, resulting in a continuous protective oxide layer, and the high diffusivity of germanium, which permits the layer to be reestablished rapidly if damaged.

### 3.21.4.2 Gold

#### 3.21.4.2.1 Anodic processes

Gold is thermodynamically stable to corrosion in ordinary aerated noncomplexing environments, and, of course, it neither tarnishes in the atmosphere nor in biological fluids. It is, therefore, ideal for applications in the decorative, medical and dental (*in vivo*), and electrical (contacts and connectors) areas. It is also used extensively (as is platinum) as a nonreactive electrode substrate for laboratory electrochemical studies of redox reactions of species in solution, however, such applications are not within the scope of this discussion.

The anodic oxidation of gold itself is of interest (indeed it is among the most studied of oxidation processes), as it can elucidate generic mechanisms for film formation and metal dissolution under anodic dissolution. In general terms, on anodic polarization in noncomplexing electrolytes, for example, sulfate, perchlorate, hydroxide, etc., gold will reversibly passivate by forming an oxide/hydroxide film above about +1.4 V (SHE) at pH 0. Thus, in sulfuric acid gold dissolves transiently to the Au(I) species but rapidly passives forming a film of hydroxide,<sup>16</sup> containing Au(III) species consisting generally of Au(OH)<sub>3</sub>. Evidence for lower oxides is no longer convincing. Conway's extensive and thorough review describes in detail the adsorption and oxidation on noble metal surfaces.<sup>17</sup> Unlike conventional corrosion, anodic oxidation on gold proceeds predominantly by surface chemical processes, involving submonolayer adsorption of hydroxide and oxide species (hydroxide electrolytes) that eventually grow by coalescence and thickening, eventually forming a macroscopic multilayer hydrous oxide film, probably by field assisted ion migration. In the presence of other anions, a competitive chemisorption with, for example, HSO<sub>4</sub><sup>-</sup>, ClO<sub>4</sub><sup>-</sup>, Cl<sup>-</sup>, occurs, which inhibits the onset of surface oxidation. Studies using scanning tunneling microscopy (STM) and atomic

force microscopy (AFM) on single-crystal gold surfaces has shown the development of single-atom dimensioned pits, and have demonstrated that atomic rearrangement (or dissolution) is more difficult from atom terraces than from edges.<sup>18</sup>

In solutions where gold forms a soluble complex ion, gold may dissolve or may passivate (depending on the concentration of the complexing ion and the potential). On anodic polarization in acidic chloride solutions, gold initially dissolves, due to formation of the AuCl<sub>4</sub><sup>-</sup> ion, at potentials greater than about +1.3 V (SHE, pH = 0), depending on the chloride ion concentration; no evidence is seen for dissolution in the Au(I) state. At higher potentials greater than about +1.6 V, gold passivates forming an oxide film.<sup>19</sup> In alkaline cyanide solutions (pH = 13), which are of obvious interest for gold extraction and in electroplating, dissolution proceeds above about -0.66 V (SHE) by competitive adsorption of the cyanide ion on gold, followed stepwise by single-electron transfer and then adsorption of another cyanide ion, leading to the formation of the Au(CN)<sub>2</sub><sup>-</sup> ion. No convincing evidence for formation of the Au(III) state, Au(CN)<sub>4</sub><sup>-</sup>, is found at higher potentials, instead passivation terminates dissolution at potentials above about +0.38 V (SHE, pH = 13) due to formation of an Au(OH)<sub>3</sub> film.<sup>20</sup>

In addition to cyanide and chloride, gold forms complexes with a number of other common species in acid or alkaline conditions, including thiosulfate, thiocyanate, thiourea, sulfite, bromide, and iodide. The anodic dissolution of gold in these environments was reviewed by Nicol in 1980.<sup>21</sup> In view of the toxicity of cyanide, there is obvious interest in using alternative leaching agents for gold recovery, and thiourea, thiocyanate, and bromide processes have been considered. Of more academic interest is the surface chemistry and electrochemistry of gold in the presence of sulfur-containing species, where many detailed studies have been carried out; however, these are beyond the scope of this section.

#### 3.21.4.2.2 Gold extraction

Since the late nineteenth century, most recovery of gold from crushed ore has been via the MacArthur-Forrest cyanidation process. This utilizes the stability of the gold cyanide complex ion (Au(CN)<sub>2</sub><sup>-</sup>:  $K = 10^{-38}$ ) to dissolve gold, which may then be recovered by electrodeposition or via zinc dust (Merrill-Crowe process).<sup>22,23</sup> The principle dissolution reaction is given by Elsener's equation:

For the sake of efficient extraction and to minimize loss of cyanide as volatile HCN, the leaching is done ideally at pH close to 10.5. The cyanidation process requires an oxidant to be present (usually dissolved oxygen), and the efficiency of extraction is reduced if insufficient oxidant is present. Other factors that reduce leaching efficiency (present in so-called 'refractory' ores) include the presence of sulfides, copper, iron, and zinc. Pretreatment of crushed ores is often required as is the use of additional oxidants (chemical or biological – i.e., sulfur oxidizing bacteria).

Once leached, the gold has to be recovered from the relatively dilute cyanide solution. One of the largest gains in efficiency of gold recovery from more dilute cyanide liquors is the absorption of the gold complex on activated carbon, and a variety of processes are in use, for example, the carbon-in-pulp process.<sup>22</sup> For cyanide processes, there is also the considerable problem of cyanide disposal. To counter this, various other processes have been considered, with some in active development. These include the use of bromine, chlorine, thiourea, and thiosulfate. Although these have advantages, much research needs to be done to optimize them. Currently, therefore, the cyanide process is generally still the most economical.

#### 3.21.4.2.3 Dealloying and nanoporous materials

Dealloying as a corrosion phenomenon has been known for over 100 years, the classical case being dezincification (i.e., selective dissolution of zinc from brass leaving a copper-rich, mechanically weak, layer). Dealloying typically occurs in an alloy where at least two of the components have relatively well-separated equilibrium potentials in the environment. In such cases, where the alloy is polarized between these values, the less noble component of the alloy is selectively dissolved, leaving the remaining more noble component. This mechanism invariably produces layers that have profoundly altered mechanical properties usually of very low fracture toughness (i.e., they are brittle). These have been found to have profound influence on many stress-corrosion cracking processes in alloys.<sup>24,25</sup> Although it was not called such, and the mechanism was not then known, dealloying was first developed as a process to produce porous nickel (by selective dissolution of aluminum from a nickel–aluminum alloy – Raney nickel), which is used a catalyst in various chemical processes.<sup>26</sup>

Selective dissolution in, for example, Cu–Au and Ag–Au alloys has been well studied in order to determine generic aspects of the dealloying mechanism in

these and other more commercially important alloys. Increasingly, controlled dealloying is being used in its own right to produce tailored nanoporous gold substrates for chemical sensing and catalytic applications. The ordered intermetallic alloy Cu<sub>3</sub>Au is an excellent template to study dealloying phenomena. At low overpotentials for copper dissolution, scanning tunneling microscopy has demonstrated 2-dimensional clustering of gold, while at higher overpotentials the surface is mostly covered by gold and effectively passivates in two dimensions, although small regions of material continue to dissolve generating 3-dimensional roughness and porosity.<sup>27</sup> Above a threshold potential, global surface roughening occurs, which is strongly influenced by adsorption of species such as sulfate, chloride, and alkyl-thiols on the surface of the gold atoms. This process has been modeled using a continuum model such that porosity during dealloying develops on a length scale that is characteristic of the surface aggregation (diffusion) of the noble metal atoms.<sup>28</sup>

The formation of nanoporosity in Ag<sub>0.7</sub>Au<sub>0.3</sub> and Ag<sub>0.65</sub>Au<sub>0.35</sub> alloys during dealloying in perchloric acid has been studied. Without halide addition, the pores were of the order of 8 nm, while with chloride, bromide, and iodide, the pore size changed, respectively, to 17, 16, and 67 nm. This coarsening can be interpreted as an increase in surface mobility of the gold atoms in the presence of halides.<sup>29</sup> Gold substrates with tailored nanostructures can thus be prepared by controlled electrochemical dealloying. Although development is still required, in particular, to resist coarsening of the porosity during application, nanoporous gold substrates have many potential applications, for example, in electrocatalysis,<sup>30</sup> fuel cells,<sup>31</sup> and chemical and biochemical sensing.<sup>32</sup>

#### 3.21.4.3 Platinum Group Metals

##### 3.21.4.3.1 Anodic processes

The PGMs are characterized by their intrinsic thermodynamic stability and in this they are similar to gold. The key difference between them is that gold remains oxide-free in aerated noncomplexing aqueous environments; however, the PGMs are predicted to retain an oxide film that contributes to their passivity. The PGMs have many important properties and applications in catalysis, which are beyond the scope of this section.

For many years, it was assumed that platinum and other PGMs were oxide-free in air and in aerated

solutions; however, the advent of rapid cyclic sweep voltammetry techniques has allowed the elucidation of the redox processes between platinum and oxygen, and this research was reviewed extensively by Conway in 1995.<sup>17</sup> After initial adsorption of oxygen-containing species, a place exchange mechanism takes place between Pt and O to effectively develop a 2-dimensional and then a 3-dimensional oxide film. Oxygen adsorption, reduction, and place exchange occur via a variety of steps, with the rate-determining processes for each part of the mechanism determined; however, a full discussion is well beyond the scope of this chapter. Like gold oxide, formation on, and dissolution of, platinum occurs as a function of crystallography. On low-index surfaces, oxide formation passivates the surfaces more easily, resulting in lower dissolution rates at higher potentials, while nanofaceted surfaces dissolve more rapidly, which is the evidence that atomic edges and corners are the main locations of dissolution.<sup>33</sup> Perhaps the most interesting finding is that although like gold, anion adsorption plays a role, it appears to be much less important, which reflects the increased stability of PGMs to complexing species such as halides, cyanides, etc.

PGMs are, therefore, extremely resistant to dissolution in almost all aqueous environments under almost all conditions. For example, and in contrast to gold and silver, high pressures and temperatures are required for the dissolution of platinum in cyanide to occur at significant rates. Table 4 shows the corrosion resistance of the PGMs in various environments; importantly, PGMs are one of the few non-polymeric materials that can successfully handle fluorides and HF without significant problems.

**Table 4** Corrosion resistance of PGMs in various environments

Environment	Ru	Rh	Pd	Os	Ir	Pt
HF (40%, 20 °C)	A	A	A	A	A	A
HCl (36%, 100 °C)	A	A	B	A	A	B
H <sub>2</sub> SO <sub>4</sub> (96%, 100 °C)	A	B	C	A	A	A
HNO <sub>3</sub> (62%, 100 °C)	A	A	D	D	A	A
HCl + HNO <sub>3</sub> (aqua regia, 100 °C)	A	A	D	D	A	D
H <sub>3</sub> PO <sub>4</sub> (100 °C)	A	A	B	D	A	A
HClO <sub>4</sub> (100 °C)			C			A
KCN (100 °C)			D			C
NaOCl (100 °C)	D	B	C	D		A

A – No attack; B – Minor attack but can be used; C – Major attack and cannot be used; D – Rapid attack.

### 3.21.4.3.2 Platinum extraction and secondary recovery

As noted earlier, ambient temperature and pressure cyanide leaching is not effective for the recovery of PGMs from crushed ore bodies. Thus, after mining and concentration by gravity and/or froth flotation, the materials are smelted on a copper–nickel matte (sulfide-rich intermediate), which is further separated into copper and nickel anode materials and are purified electrolytically. The PGMs remain within the (insoluble) anode slime and were traditionally recovered using wet chemical methods, including sequential precipitation. Current technology uses a liquid–liquid solvent extraction technique that is more efficient, offering enhanced recovery and lower cost.<sup>34</sup>

Efficient secondary recovery of PGMs from, for example, vehicle exhaust catalysts, and recovery and separation from other metals from, for example, electronic circuit boards, is critical for their sustainable use. In such cases, higher temperatures and pressures, as well as more corrosive solutions, can be used. Several leaching processes have been proposed, the majority using strong hydrochloric acid containing an oxidant (i.e., aqua regia)<sup>35,36</sup> at high temperature and pressure leaching with cyanide.<sup>37,38</sup> The pressure cyanide processes are better developed and can, under ideal conditions, extract over 95% of the platinum and palladium and about 85–90% of rhodium.

### 3.21.4.3.3 Cathodic processes: Hydrogen evolution

The PGMs are well-known for their outstanding electrocatalytic activity, especially for the evolution of hydrogen. The exchange current density for the overall hydrogen evolution reaction

varies by about 10 orders of magnitude from mercury and lead to platinum (Table 5).

The large exchange current density of PGMs implies a correspondingly low overpotential for hydrogen evolution. This property finds extensive applications in electrocatalysis in general, and in hydrogen storage and release, hydride batteries, and fuel cells, where nanosized PGM particles are used, to increase surface area and to reduce the quantity of expensive material used. An important application is noble metal alloying of passive metals (stainless steels and titanium), where small amounts (0.2%) of noble metals (typically Pt, Pd, or Ru) causes spontaneous passivation in acids by increasing the cathodic rate of hydrogen evolution.

**Table 5** Exchange current densities for the evolution of hydrogen on various metals in various environments

Environment	Metal	Exchange current density, $i_o$ ( $A\text{ cm}^{-2}$ )
1 M $\text{H}_2\text{SO}_4$ at 20 °C	Palladium	$10^{3.0}$
	Platinum	$10^{3.1}$
	Rhodium	$10^{3.6}$
	Iridium	$10^{3.7}$
	Nickel	$10^{5.2}$
	Gold	$10^{5.4}$
	Titanium	$10^{8.2}$
	Aluminium	$10^{-10.0}$
0.1 M HCl at 20 °C	Lead	$10^{12.0}$
	Mercury	$10^{12.3}$
	Platinum	$10^{-2.6}$
	Palladium	$10^{-3.2}$
	Silver	$10^{-5.6}$
	Gold	$10^{-5.6}$
	Iron	$10^{-6.0}$
	Nickel	$10^{-6.0}$
	Copper	$10^{-6.8}$
	Lead	$10^{-13.2}$

Bockris, J. O. M.; Reddy, A. K. N. *Modern Electrochemistry*, 2nd ed.; Springer, 1998.

The PGMs are somewhat susceptible to a reduction in their catalytic activity as a consequence of 'poisoning' with other surface active species, including metallic impurities with lower exchange current density, which will tend to plate out onto cathodically polarized surfaces.<sup>39</sup> On the other hand, noble metal oxides, in particular, ruthenium and iridium oxide, are almost as effective cathodic electrocatalysts as platinum and palladium; they are almost immune to poisoning by metal ions in solution.<sup>40,41</sup>

### 3.21.5 High temperature Properties

#### 3.21.5.1 Silver and Gold

Owing to their relatively low melting points and mechanical strengths, silver and gold find very few applications at elevated temperatures. Silver below its melting point has considerable resistance to oxide-film formation, but molten silver dissolves appreciable quantities of oxygen, which precipitates as silver oxide or bubbles dispersed throughout the metal when the metal solidifies. Gold is not subject to oxide-film formation at any temperature up to its melting point, but may be covered by a thin adsorbed layer of oxygen. The absence of an oxide film enables gold to be pressure-welded at room temperatures.

#### 3.21.5.2 Platinum Group Metals

The excellent resistance of platinum, rhodium, and iridium to oxidation at high temperatures finds numerous applications in technology, in particular, in the form of platinum-based alloys. Osmium and ruthenium form volatile oxides and are therefore not suitable for high temperature use on their own.

Platinum, while it does not form a measurable oxide film, is covered by thin adsorbed layer of oxygen,<sup>42</sup> which volatilizes at an increasing rate as its temperature rises above 1000 °C, via a volatile metastable oxide.<sup>43</sup> In the presence of flowing oxygen or air, the rate of volatilization is considerably increased. Rhodium, iridium, and palladium exhibit oxide-film formation, at a temperature as low as 600 °C.<sup>44</sup> However, palladium oxide dissociates above 870 °C, the metal then appearing bright up to its melting point. Absorption of oxygen without film formation occurs, however, and palladium increases in weight. Platinum loses more mass via this volatilization mechanism compared with rhodium and iridium, from 900 to 1200 °C, but their volatilities are about the same at temperatures around 1300 °C. However, below 1100 °C, alloys of platinum with rhodium and palladium lose less mass than do pure platinum, but palladium-platinum alloys absorb oxygen detrimentally. Rhodium-platinum alloys at high temperatures show no preferential loss of either metal, and are widely used. Iridium-platinum alloys show greater loss of weight on heating in air, because of the greater rate of oxidation of iridium and the higher volatility of the oxide of this metal. Iridium is thus lost preferentially from iridium-platinum alloys. Selected properties of the PGM oxides are shown in Table 6.

Volatilization of platinum and its alloys at high operating temperatures may be substantially reduced by avoiding contact with air or oxygen, especially if the environment is flowing, for example, due to convection currents. This may be achieved by completely embedding the metal in high-purity alumina refractory; flame-sprayed coatings, for example, are effective in preventing free circulation of air over the metal. Only alumina that is largely free from silica and other oxides that are more easily reduced can be used, otherwise contamination and embrittlement of the platinum may result from partial reduction of such oxides.

Grain growth of platinum and its alloys when operating continuously at high temperatures is often responsible for failure of the metal, resulting from weaknesses developed by large intercrystal boundaries. This defect may be largely eliminated by the use of

**Table 6** Selected properties of PGM oxides

Oxide	Molar Mass	Density	Pilling–Bedworth ratio	Properties at high temperature
RuO <sub>2</sub>	133.1	6.97	2.31	Dissociates at 930–950 °C
RuO <sub>4</sub>	165.1		–	Sublimes at 40 °C
RhO	118.9			Dissociates above 1000 °C
Rh <sub>2</sub> O <sub>3</sub>	253.8	8.2	1.87	Dissociates above 1100 °C
PdO	122.7	8.31	1.66	Dissociates above 870 °C
OsO <sub>2</sub>	222.2	11.29	2.33	Dissociates at 650 °C
OsO <sub>4</sub>	254.2	4.95	6.09	Boils without decomposition at 131 °C
IrO <sub>2</sub>	224.2	11.69	2.24	Decomposes at 400 °C
PtO	211.1	14.9	1.56	Dissociates above 1100 °C
Pt <sub>3</sub> O <sub>4</sub>	649.3	8.89	2.68	Decomposes when heated
PtO <sub>2</sub>	227.3	10	2.63	Thermally unstable

sintered metal produced by powder-metallurgical techniques, or by the incorporation of a small amount of a refractory oxide, carbide, or nitride in powder form in the body of the metal, such as zirconia-dispersed platinum–rhodium alloys.<sup>44</sup>

### 3.21.6 Selected Applications

#### 3.21.6.1 Chemical Process Equipment

##### 3.21.6.1.1 Linings

Traditionally, noble metal linings were used in chemical and pharmaceutical production as linings for steel and copper equipment and occasionally as vessels, condensers, and other equipment. However, such uses have generally been superseded either by more cost-effective coating materials (e.g., tantalum, glass lining), or alternative construction materials (e.g., stainless steel, graphite).

Linings may be of two types: either loose or bonded. Loose linings provide good contact between vessel and lining – adequate for good heat transfer – but are not suitable to be used in reduced pressure as the gap between vessel and lining will expand causing the lining to fail. Traditionally, silver linings for chemical plant were used particularly for highly alkaline environments in which silver has excellent performance; where used, silver linings are generally 0.5–1 mm thick. Solid silver construction, 1–2.5 mm thick, may be employed for condenser coils, distillation heads, etc. Traditional bonded silver linings for mild steel or copper vessels are generally soldered *in situ* onto the walls of the vessel using a tin–silver solder. Such soft-soldered linings should not exceed 200 °C for their maximum continuous operating temperature. However, bonded linings are suitable

for operation under vacuum conditions, and provide excellent heat-transfer characteristics.

Platinum, rhodium–platinum, and iridium–platinum alloys are employed in line and sheath autoclaves,<sup>45</sup> reaction vessels and tubes, calorimeters,<sup>46</sup> and a range of other laboratory and commercial equipment.<sup>47</sup> Linings are generally 0.13–0.38 mm thick, and for certain applications coextruded platinum-lined nickel-based alloys (Inconel 625), or other metal reactor or cooling tubes are fabricated. In such cases, the platinum is bonded to the base metal, but in all other instances platinum linings are of the ‘loose’ type.

##### 3.21.6.1.2 Bursting discs

Bursting discs are a simple and effective (fail-safe) protection against overpressurization in a closed system. The protection of pressure vessels containing corrosive materials presents a special problem for the selection of bursting discs as bursting discs should not corrode (and hence weaken) until they are required to fracture under an overpressure. For this reason, corrosion resistant, high reliability bursting discs have been traditionally fabricated from noble metals,<sup>48</sup> although other cost-effective alternatives now exist (e.g., tantalum or niobium). The recommended maximum temperatures for continuous use are 80 °C for gold, 150 °C for silver, 300 °C for palladium, and 450 °C for platinum.

##### 3.21.6.1.3 Spinnerets

The spinning of viscose rayon for the production of yarn, tire cord, and staple fiber involves the extrusion of an alkaline solution of cellulose into an acid bath. The orifices through which individual fibers are extruded are often extremely small – down to

30  $\mu\text{m}$  or less in diameter – and their dimensional accuracy must be maintained to a very high degree for long periods, while operating in two highly corrosive media simultaneously. Platinum–gold alloys are the traditional material of construction for rayon spinnerets, in particular, Au–30Pt + 0.5Rh as a grain-refining additive. This alloy has greater hardness, which permits a high polish to be produced in a scratch-resistant exit face, while the small grain size ensures that the holes produced have a high grade of uniform circularity. Other noble metal alloys for spinneret construction include rhodium–platinum, iridium–platinum, iridium–rhodium–platinum, ruthenium–platinum, ruthenium–palladium, and platinum–palladium. The use of these alloys in this application is being superseded by the introduction of tantalum, which has comparable corrosion resistance at lower cost.<sup>49</sup>

### 3.21.6.2 High temperature Materials

#### 3.21.6.2.1 Molten glasses and salts

A principal application of PGM metals is in the production of fine, optical glasses and glass fibers; platinum–alloy crucibles and spinnerets are generally resistant to molten glasses at temperatures from 1200 to 1500 °C, with continuous operation at 1400 °C. Traditionally, Pt–Rh alloys were used for this purpose with typically 10% Rh added to improve high temperature creep-rupture performance and to reduce evaporation loss. Useful gains in creep-rupture properties can be made using zirconia-dispersed materials, either of pure platinum or of Pt–10Rh alloy.<sup>2</sup> Materials may be used as sheet for fabricated metal crucibles, as thin foil liners for covering ceramic (i.e., alumina) crucibles, and as flame-sprayed coatings<sup>50</sup> on a ceramic substrate. Also, flame-sprayed or plasma-evaporated alumina coatings can be used to protect PGM materials from evaporation losses at high operation temperatures.<sup>51</sup>

Platinum is generally highly resistant to air-saturated oxide glasses because of the formation of a thin stable layer of oxide that passivates the metal.<sup>52</sup> Stressing during immersion in molten glass (and hence cracking the passive oxide) greatly increases the dissolution rate of the metal in the glass.<sup>53</sup> Under reducing conditions, for example, nonoxide glasses and/or with an inert gas atmosphere, platinum is much less resistant to molten glass, with increased dissolution and additional reaction to form embrittling intermetallic compounds.<sup>54</sup> Where platinum cannot be used, or where

even higher temperatures are required (1500–2000 °C), iridium crucibles can be used.<sup>55</sup>

Platinum crucible materials are also generally suitable for containing molten salts over similar temperature ranges as for molten glass. However, salts that can easily form complex ions with platinum will cause its corrosion; also, coupling to other metals can result in enhanced dissolution if it encourages the formation of the complex ionic species in the melt.<sup>56</sup> Platinum and iridium crucibles and equipment are extensively used in single crystal growth production from molten precursors.

#### 3.21.6.2.2 Metal joining

Solders and brazes (although the distinction is not clear, solders are useful for ‘lower’ temperatures, while brazes are suitable for ‘higher’ temperatures) are widely used materials for metal joining. Their key characteristics are that

1. their melting point is lower than the parent material to be joined;
2. a metallurgical bond, usually by intermetallic development or interdiffusion, is formed between the solder and the parent material.

One common formulation of a tin-based lead-free solder contains several percent silver and is more corrosion resistant than the material it replaces. For use in higher temperature, silver-based brazing alloys are widely used. In both cases, galvanic corrosion of the parent (joined) material should be considered as the joining alloy is commonly significantly more noble. Thus, where silver brazing alloys are used to join stainless steel, a narrow zone of corrosion on the stainless steel often occurs on subsequent exposure in tap water.<sup>57</sup>

PGM brazing alloys, commonly containing palladium with alloying additions, including gold, silver, nickel, copper, are also utilized. They have significant advantages, including high temperature strength and stability as well as corrosion resistance, and have been used to join stainless steels,<sup>58</sup> nickel-based superalloys,<sup>59</sup> and other refractory materials, with minimal corrosion problems. Their low vapor pressure gives them advantages in high vacuum systems, and their low toxicity (if nickel-free) gives them advantages as a dental brazing alloy.<sup>60</sup>

#### 3.21.6.2.3 Furnace windings

Rhodium–platinum alloys containing up to 40% Rh have been traditionally used in the form of wire or

ribbon in electrical resistance windings for furnaces to operate continuously at temperatures up to 1750 °C. Such windings are usually completely embedded in a layer of high-grade alumina cement or flame-sprayed alumina to prevent volatilization losses from the metal due to the free circulation of air over its surface. However, these types of furnace windings have been largely superseded by molybdenum disilicide materials, which are resistant in air at a similar temperature. For reducing (hydrogen) atmospheres, Pt–Rh alloy windings are still useful, although molybdenum metal windings may also be used at considerably lower cost.

#### 3.21.6.2.4 Temperature measurement

Until 1968, platinum–rhodium thermocouples (type S) were used as the standard interpolating thermometer in IPTS-68 (International Practical Temperature Scale of 1968) because of their good thermal stability. However, the present temperature scale ITS-90 (International Temperature Scale of 1990) now uses a Standard Platinum Resistance Thermometer.<sup>61</sup> The particular advantages of PGM materials in temperature measurement are, of course, their excellent stability to oxidation and corrosion. Thus, platinum resistance thermometers offer a more reliable temperature measurement than the traditional thermocouples up to around 600–650 °C and are unaffected by the environment. At higher temperatures, Pt/Pt–10Rh (type S) or Pt/Pt–13Rh (type R) thermocouples may be used for accurate temperature measurement in essentially all atmospheres up to 1450 °C. Both types of thermocouple have a short-term stability, typically better than 0.5 °C, with a long-term reproducibility of better than 2.0 °C. For higher temperatures up to 1800 °C, Pt–6Rh/Pt–30Rh (type B) thermocouples can be used.

#### 3.21.6.2.5 Gas turbine applications

Improvements to gas turbine operating efficiency require an increase in the gas temperature of the turbine and combustion chamber. Since most gas turbine materials are now optimized more for their high temperature strength and creep resistance, their hot corrosion and oxidation resistance has become relatively poorer. Platinum aluminide coatings have been developed, which, in combination with other coating types, offer improved performance for nickel-based superalloys.<sup>62</sup> Platinum, by substituting for nickel in the aluminide, eliminates chromium-rich precipitates from the outer coating layer and

limits the diffusion of refractory transition elements such as molybdenum, vanadium, and tungsten into the outer coating layer.<sup>63</sup>

### 3.21.6.3 Dental and Medical Applications

#### 3.21.6.3.1 Dental restorations

Generally, the noble metals, particularly gold, have excellent biocompatibility, and the use of gold and gold–palladium alloys in dental restorations is very common. However, they are too soft to be used on their own and require alloying (typically with copper, silver, and palladium, plus other minor components), and this increases corrosion susceptibility. There are a number of classification schemes for these alloys: First, based on their strength, and second, on their metal content. There are numerous alloys, many proprietary and many designed for specific aspects of the dental restoration task; the main classes are listed in Table 7.

The oral environment is corrosive and materials for use must be correspondingly corrosion resistant; thus, the general corrosion of dental alloys is of interest partly with a view to increase the service life of implants and partly for biocompatibility. The main issues are

1. tarnishing and discoloration, usually caused by foods and drinks that contain sulfur;<sup>64</sup>
2. galvanic corrosion between adjoining oral alloys of differing composition;<sup>65</sup>
3. galvanic corrosion caused by microsegregation of alloy components at grain boundaries or in the interdendritic regions in cast materials.

Failure modes exhibited include generation of expansive corrosion products causing disbonding of the implant, general thinning of the material, and cracking.

**Table 7** Classification for dental alloys

	<i>Yield stress (MPa)</i>	<i>Elongation (%)</i>
Type I	<140	18
Type II	140–200	18
Type III	200–340	12
Type IV	>340	10
Typical composition		
High noble	Au > 40% + total noble metals > 60%	
Noble	Total noble metals > 25%	
Base	Total noble metals < 25%	

Source: Wataha, J. C. *J. Prost. Dent.* **2002**, 87, 351–363.

Conventional mercury amalgam restorations are typically anodic to noble and more noble alloys and will corrode preferentially<sup>66</sup> and can lead to cracking. Therefore, care has to be taken in mixing restorative alloy materials. For example, cracking of gold crowns has been observed as a consequence of intergranular–interdendritic corrosion in association with corrosion of an underlying mercury-based amalgam alloy.<sup>67</sup> Electrochemical and corrosion tests in ammonium and sodium sulfide solutions, as a simulation of the oral environment, has demonstrated that the tarnishing is particularly related to the silver and copper contents of the alloys.<sup>68</sup> Generally, as might be expected, the higher the noble metal content of the alloy used, the more the corrosion resistant,<sup>69</sup> hence, selection of the correct restorative alloy is a balance between mechanical and other required properties and corrosion resistance.<sup>70</sup>

### 3.21.6.3.2 Medical sensing and electrodes

Unalloyed noble metal (or high noble metal content) body implants are used for a number of purposes, with generally few or no corrosion issues arising. Reference above has been made to the production of nanoporous gold electrodes of exceptionally high surface area. These have a number of potential applications in medical sensing; for example, insulin determination.

Noble metals, particularly platinum and platinum alloys, find use as electrode materials for *in vivo* nerve stimulation (e.g., heart, neural, auditory electrode implants, etc.). The applied potentials used are generally transient in nature (i.e., a pulse waveform), and significant corrosion of electrode materials can be observed. For example, Pt, Au, Rh, Ir, Pt–10Ir, and Pt–10Rh electrodes were severely corroded under a bipolar current pulse of  $1 \text{ A cm}^{-2}$ , while Rh was moderately attacked. At  $0.1 \text{ A cm}^{-2}$ , Au, Rh, and Ir were resistant to corrosion.<sup>71</sup> However, although examination of heart pacemaker electrodes has shown evidence of corrosion in all cases, in no case had this resulted in the failure of the implant.<sup>72</sup>

### 3.21.6.4 Electrical Contact Materials

High reliability electrical contacts are frequently plated with noble metals (Ag, Au, Pd, etc.) in order to limit any corrosion and consequent increase in contact resistance with time. This is because uncoated copper contact materials are particularly susceptible to corrosion and contact failure mechanisms involving vibration (e.g., in motor vehicles), giving rise to wear–fretting effects in addition to corrosion.

Silver coatings are liable to grow intrusive whiskers in sulfidizing, and to a lesser extent in chloridizing environments, although much less than copper or tin. The main environmental driver is the presence of hydrogen sulfide at or above 200 ppb, which can be reached, for example, in pulp and paper processing,<sup>73</sup> where significant failures have occurred.

Gold alloys and gold coatings are also extensively used for electrical contacts, especially in the electronics industry. Corrosion failure mechanisms are associated with the growth of gold shorts from cathodic conductors, especially where chloride ions are present. On anodically biased conductors, a voluminous reaction product of  $\text{Au}(\text{OH})_3$  is produced by anodizing.<sup>74,75</sup>

### 3.21.6.5 Anodes

#### 3.21.6.5.1 Dimensionally stable anodes

Nonconsumable anode materials are used extensively in electroplating, electrowinning, chlorine production, and water electrolysis (oxygen evolution) and have traditionally variously utilized silver, lead, magnetite, graphite, and noble metals. Of these, chlorine production by electrolysis of brine is among the most energy intensive and industrially important.

For chlorine evolution, platinum generally shows very low rates of attack, and platinum anodes can be used for both cathodic protection in seawater and for chlorine production at low overvoltage.<sup>76</sup> This attribute takes advantage of using platinum-coated titanium or niobium substrate materials; the substrates are stable to the conditions of electrolysis, while the electrode reaction (e.g., chlorine evolution) occurs on the platinum surface. At low current densities, the platinum can be corroded, especially at low pH; however, at high current densities, passivation of the platinum occurs and corrosion reduces considerably. However, the corrosion rate of platinum can be much higher if an alternating current component is present, as this tends to thicken the passive film. Rhodium and iridium are as resistant to anodic corrosion as platinum, but are more resistant to the influence of alternating currents.

The single most important advance in anodes for chlorine evolution is in the replacement of noble metal coatings on stable substrates with oxide coatings using ruthenium modified by iridium ('mixed metal oxides').<sup>77</sup> These provide efficient production of chlorine at low overvoltage, with no corrosion, provided the overpotential is kept below a critical value.<sup>78</sup> Such anodes are called 'dimensionally stable'

because, in principle, they do not need replacement throughout the life of the plant, provided they are operated within the correct parameters.<sup>79</sup> They are also responsible for a reduction of about 20% in the energy usage per unit of chlorine production.

Given the success of noble metal oxide-doped anodes in chlorine evolution, they are being trialed in a number of other applications that would benefit from improved electrocatalysis.

### 3.21.6.5.2 Cathodic protection

Although there are a wide range of possible anode systems for impressed current cathodic protection, noble metal-coated titanium mesh anodes have been used for many years in a wide variety of applications, including protection of reinforcement steel in concrete and cathodic protection systems in seawater (e.g., for vessels, etc.). In severe environments, or where the system requires a high driving voltage, platinum-coated niobium anodes are used because of the increased stability of niobium (compared with titanium) to chlorides. More recently, the use of noble metal oxide-coated electrodes has also become increasingly important, with their advantages of higher current density and increased lifetime under polarization.<sup>80</sup>

### 3.22.1 Introduction

Pt-group metals (PGMs), together with silver and gold, constitute the group known as noble metals. These metals find wide application in a number of different fields, such as catalysts, fuel cells and metal winning electrodes, dental alloys, and even semiconductors. The focus of this chapter will be limited to the addition of PGMs, and in some cases silver and gold, to Cr-based stainless steel alloys used in process industries where prevailing reducing acid conditions create major challenges for the corrosion resistance of equipment construction materials, and failures as a result of corrosion can create serious safety hazards and cause substantial maintenance and production losses. It will also not consider PGM-based alloys in which the majority of alloying elements consist of the PGM, although these alloys are becoming increasingly important for high temperature corrosion resistant applications. Two excellent reviews appeared recently<sup>1,2</sup> describing the manufacturing of such alloys, as well as their physical, mechanical, and corrosion properties.

Owing to the very specialized nature of the topic under discussion, it is not surprising that research on the addition of noble metals to alloys for the improvement of corrosion resistance, or cathodic alloying of materials, has not been widely investigated or described in literature. Another reason might be that the major producers of the PGMs used in the enhancement of corrosion resistance, namely Pd (Pd) and Ru (Ru), have traditionally been South Africa and Russia (old

USSR), and they are the obvious beneficiaries of an increased demand for their produce should this approach of adding PGMs to stainless steels markedly increase the demand for the elements in question. It seems that research work on this was mainly done by the Tomashov's group (in Russia), Higginson and others at Mintek (Council for Mineral Technology, South Africa), the University of the Witwatersrand in collaboration with Mintek, and Tjong and coworkers in Hong Kong. As a result, there has been little discussion of the topic in the literature, and no comprehensive review paper on the subject appeared to date. The present review, therefore, covers previous work carried out by various groups from different laboratories and, in addition, discusses some more recent results from the past two decades. Furthermore, this review will be restricted to aqueous corrosion in reducing acid media, and will not specifically consider high temperature corrosion resistance of cathodically modified stainless steels. Conclusions are drawn from earlier results, and possible areas for future research are outlined.

### 3.22.2 Cathodic Modification and Passivation

During the course of the past 50 years, a number of papers concerning the application of cathodic modification and the corrosion behavior of cathodically modified alloys have been published, especially by the Tomashov group in Russia. However, none of these provides a comprehensive description of the electrochemistry of the cathodic modification phenomenon and of the mechanisms involved. One of the purposes of this review, therefore, is to present in detail all aspects concerning the electrochemistry of cathodic modification. The practical applications of cathodic modification in different alloy systems, and the corrosion behavior of cathodically modified alloys in different acidic media, will be dealt with later in the review.

An examination of the mechanisms of corrosion processes by Tomashov<sup>3</sup> indicates that there are four possible ways in which corrosion-resistant alloys can be produced and the resistance of alloys against electrochemical attack increased, namely:

- an increase in the degree of thermodynamic stability;
- retardation of the kinetics of the cathodic processes;
- retardation of the kinetics of the anodic processes; and
- the production of stable passivating oxide layers.

The thermodynamic stability of commercial steels can be increased in only a limited number of cases, for example, Cr-containing steel can be alloyed with a nickel or molybdenum.<sup>3,4</sup> Cathodic reactions can be retarded in two ways: by the elimination of active cathodic impurities, such as iron or copper in zinc, from alloys and by the increase of overvoltage of the cathodic process, for example, by the alloying of manganese or zinc to magnesium alloys, and of arsenic or antimony to steel. Stable passivating oxide layers can be obtained by adding Cr, which is thermodynamically less stable than iron, to iron to produce stainless steel which owes its corrosion resistance to the formation of passivating oxide layers on the surface of the steel. Retarded cathodic reactions can change the polarization curves as shown in **Figure 1**.

The anodic reaction can be retarded as a result of an increase in the ability of the alloy to be passivated. This can be done in various ways, including the alloying of iron, nickel and ferronickel steels with Cr, or the introduction of active cathodes into the alloy, for example, the alloying of stainless steels and titanium with PGMs. The latter technique is known as cathodic modification.

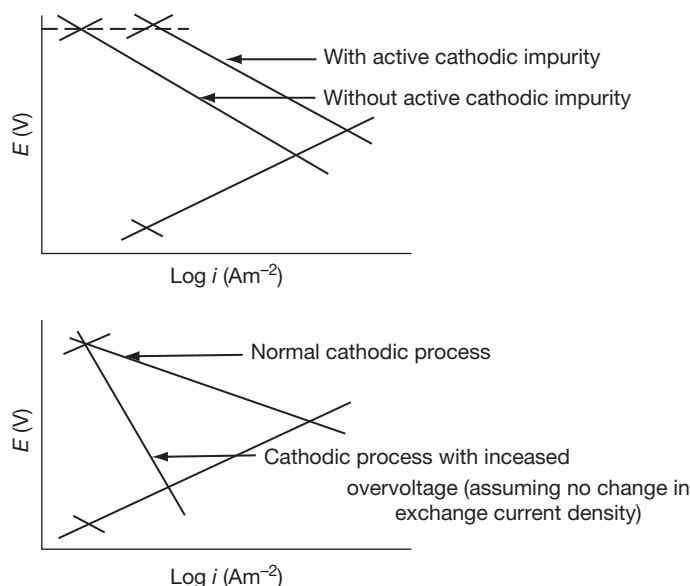

### 3.22.3 Origin of Cathodic Modification

Cathodic modification is not widely known and practiced outside USSR, but it is by no means a new

discovery or concept. As early as 1911, Monnartz<sup>5</sup> reported that the rapid corrosion of Fe–Cr alloys in certain acids can be prevented either by the winding of a Pt wire around the sample used in the corrosion test, or by the alloying of the steel with Pt. Nobody seems to have shown much interest in this discovery until Tomashov *et al.*<sup>6</sup> first confirmed it in 1948, and then further developed the concept of ‘cathodic alloying’ in their work on stainless steels and titanium and its alloys. Other contributions have been made mainly by Stern and coworkers<sup>7–11</sup> and Cotton.<sup>12–15</sup>

In principle, passivity can be induced in a base metal or an alloy by the addition of a noble metal (one of the PGMs, gold, or silver) having a high cathodic exchange current density, provided that the passive region of the base alloy extends to potentials that are more negative than the redox potential of the environment. This is schematically represented in **Figure 2**, in which line A represents the cathodic polarization curve for the metal and B, the cathodically modified alloy. Hence, for metals and alloys that exhibit stable passivity at potentials sufficiently more negative than the existing hydrogen potential in the system, spontaneous passivation will be possible in the absence of any substance or compound more oxidizing than hydrogen ions. The effect of cathodic modification should therefore be most pronounced in nonoxidizing acid environments, for example, deaerated hydrochloric and sulfuric acids.

This conclusion has been confirmed by Greene *et al.*<sup>11</sup> who found that, while addition of PGMs to Cr

**Figure 1** Schematic representation of ways in which cathodic reactions can be retarded.

**Figure 2** Schematic illustration of the effect of cathodic modification. A is the cathodic polarization curve for the parent metal, while B is the cathodic polarization curve for the cathodically modified alloy.

in nonoxidizing acids (hydrochloric and sulfuric acids) improved its corrosion resistance, they had a detrimental effect in oxidizing acid (nitric acid) because the oxidizing acid increased the potential to a value in the transpassive range.

### 3.22.4 Requirements for Cathodic Modification

The basic conditions required for successful cathodic alloying can be summarized as follows<sup>3</sup>:

- The base alloy must have a small critical current density ( $i_{cr}$ ) that will be easily exceeded by the current of the hydrogen cathodic reaction on the added noble metal at the given passivation potential ( $E_p$ ).
- The passivation potential ( $E_p$ ) of the base metal must be sufficiently negative to allow the cathodic component that has been introduced to change the corrosion potential ( $E_{co}$ ) of the alloy to a value in the passive range that is more positive than ( $E_p$ ) but less positive than the potential associated with the onset of transpassive processes ( $E_{tr}$ ).
- The transpassive potential ( $E_{tr}$ ) of the base alloy should be sufficiently electropositive to allow a wide passive range.

Furthermore, the cathodic alloying component should itself satisfy certain basic conditions<sup>3</sup>: it should have a higher exchange current density  $i_0$  (and lower overvoltage) for the cathodic process of hydrogen evolution than the base metal or the alloy, and it should be corrosion resistant under the given

conditions. In nonoxidizing acids (such as sulfuric and hydrochloric acids), the conditions requiring a sufficiently negative passivation potential are satisfied by stainless steels, Cr-based alloys and titanium-based alloys, while the PGMs have the necessary high exchange current density,  $i_0$  (and low overvoltage), for hydrogen evolution.

### 3.22.5 Principle of Cathodic Modification

**Figure 3** presents schematic diagrams of the four distinct states that can be displayed by a system with an active–passive transition. The different states depend upon the relative efficiency of the cathodic process (or processes) in each case.

#### 3.22.5.1 Active State

When the rate of the cathodic process is relatively low (as shown by the solid line in **Figure 3(a)**), the system will be in the active state. The metal or alloy undergoes stable active dissolution at a potential of  $E_{co}$  with a current density of  $i_{co}$ , and the following conditions prevail:

$$E_O^A < E_{co} < E_p \text{ and } i_{cath}(E_p) < i_{cr}$$

The active state is established spontaneously. Hence, if an external perturbation causes the system to move momentarily into the passive potential range, the active state will be spontaneously reestablished.

#### 3.22.5.2 Active–Passive State

For a higher, intermediate rate of the cathodic process (as shown by the solid line in **Figure 3(b)**), there are three possible conditions for the system. These conditions are given at the three points A, B, and C at which the cathodic line and anodic curve intersect.

At potential C ( $E_p$ ), anodic dissolution of the metal or alloy occurs at a relatively high corrosion rate. At potential B ( $\sim E_p$ ), the system is in an unstable state rarely observed in practice. At potential A ( $> E_p$ ), the system is in the passive state, and the corrosion rate is very low. If the system is perturbed, the different conditions of the active–passive state will not be spontaneously reestablished.

#### 3.22.5.3 Passive State

For a high rate of the cathodic process (as shown by the solid line in **Figure 3(c)**), the anodic and cathodic

**Figure 3** Different active-passive status in an alloy system.

curves intersect at only one point. The system is in a stable, passive state. The following conditions prevail:

$$E_O^C > E_p \text{ and } i_{cath}(E_p) < i_{cr}$$

The rate of metal or alloy dissolution is very low and is equal to the passive current density  $i_p$ . The passive state is also spontaneously stable, which means if the passivity is momentarily disturbed, the passive state will be spontaneously reestablished.

This kind of system is typical of cathodically modified Cr, stainless steel, and titanium alloys in nonoxidizing acid environments. The Cr, stainless steel, and titanium alloys all have passivation potentials more negative than the evolution potential of hydrogen in acidic media. When a PGM is added to any of these alloys, a large increase in the rate of hydrogen evolution will occur, which is large enough to move the corrosion potential of the cathodically modified alloy in the region of stable passivity. Spontaneous passivation of the alloy will therefore be the result.

#### 3.22.5.4 Transpassive State

For a very high rate of the cathodic process (as shown by the solid line in **Figure 3(d)**), or in highly oxidizing environments, it is possible that  $E_O^C > E_{tr}$ . At this high potential, the metal or alloy will have a higher rate of dissolution than it will at potentials in the passive range, and considerable corrosion can take place.

A comprehensive study by Stern and Wissenberg<sup>8</sup> on the effect of various PGMs and other noble metals in causing the spontaneous passivation of titanium in boiling dilute sulfuric and hydrochloric acids showed that the increase in corrosion resistance of the titanium depends on the concentration of the PGMs added and also that alloying additions of as little as 0.1% (by mass) resulted in a pronounced improvement in corrosion resistance. They found that the effect of the various alloying elements in improving the corrosion resistance of an alloy generally decreased in the order:

$$Ir > Rh > Ru > Pt > Pd > Os > Au > Re$$

According to the available comparable data, there seems to be a reasonable parallel between the hydrogen exchange current densities and the extent to which additions of the various PGMs improve corrosion resistance, although a close examination shows that exceptions do occur, and that this agreement is not conclusive.<sup>16</sup>

The relatively high exchange current density of Pd indicates that it should be an effective alloying element in conferring stable passivity. Although equivalent data under these conditions are not available for Ru, it is widely considered to be a more effective cathode for hydrogen evolution than is Pd. It should therefore be a fairly effective cathodic modifying agent. Streicher<sup>17</sup> tested Pd, Pt, iridium, osmium, rhodium, and Ru as cathodic additives to ferritic

stainless steels, and showed that Ru additions (0.2%) indeed produced better corrosion resistance than did Pd additions (0.2%). Higginson<sup>18</sup> also confirmed that Ru confers better corrosion resistance on ferritic stainless steels than does Pd. The commercial titanium alloy Ti–0.2% Pd containing 0.2% Pd which was developed by the Tomashov group proves that cathodically modified alloys can be economically viable corrosion resistant materials for severe reducing conditions.

### 3.22.6 Mechanism of Cathodic Modification

Upon formation of the alloy, it is conceivable that the atoms of each alloying component maintain their electrochemical individuality. Consequently, although it is a solid solution, the surface of the alloy is electrochemically heterogeneous at an atomic level, and the atoms of the solid solution do not possess identical corrosion resistance. It seems that the PGMs can inhibit corrosion in two ways, namely;

- by acting as a catalyst for hydrogen evolution (and thus increasing the efficiency of the cathodic process); and
- by inhibiting the anodic dissolutions of the metal or alloy to which they are added.

As a result of the initial interaction of the different atoms of the alloy with the corrosive media, there is a rearrangement of atoms at the alloy surface resulting in a redistribution of the PGM on the surface of the alloy, before passivity is established.<sup>19,20</sup> Three separate mechanisms have been proposed<sup>18</sup> to account for the distribution process, namely:

- dissolution of the PGMs followed by diffusion through the electrolyte and, secondarily, electrochemical deposition of the noble metal on the alloy surface;
- volume diffusion (from the bulk alloy) of the PGM atoms; and
- surface diffusion of the PGM atoms.

The dissolution–deposition model was proposed in some early research into the cathodic modifications of titanium alloys.<sup>15</sup> Diffusion of the PGM ions (or complexes) through the electrolyte to the surface of the alloy could easily occur at a sufficient rate to account for the observed redistribution. However, it is impossible for the PGMs to be oxidized in the potential range associated with the dissolution of the

cathodically modified alloy, and this fact is a major obstacle, providing a fundamental objection to this mechanism.

The volume-diffusion and surface-diffusion mechanisms do not involve dissolution of the PGM, although the latter model does not preclude the possibility of partial solvation of PGM atoms. However, the difficulty initially associated with these mechanisms was that the diffusion rates associated with similar processes were not high enough to account for the redistribution of PGM atoms at relatively low temperatures. This objection remains valid for the volume-diffusion mechanism.

The important feature of the surface-diffusion mechanism concerns the nature of the surface undergoing anodic dissolution. In recent years, an increasing amount of evidence has emerged which favors the surface-diffusion mechanism in alloying systems that undergo selective dissolution. Forty and Durkin<sup>21</sup> showed that, for silver alloys containing 10 at.% gold, the surface diffusion of the more noble component of the alloy (gold) is responsible for substantial reordering of the surface during anodic dissolution in nitric acid. Pickering<sup>22</sup> classified the polarization curves of alloys in terms of their tendency towards selective dissolution and the surface enrichment of the more noble metal. He also pointed out that the morphology of cathodically modified alloys should be that of a solid planar surface enriched in the noble metal. Work by Tomashov *et al.*<sup>23,24</sup> on cathodically modified alloys has also provided evidence in favor of a surface-diffusion mechanism.

A surface undergoing anodic dissolution is an extremely disturbed surface because selective dissolution causes a high concentration of defects in the surface. This, in turn, can cause rapid diffusion of the atoms of the noble-metal component to the surface of the alloy. Normally, diffusion coefficients associated with surface diffusion are considerably higher than those for volume diffusion, particularly at ambient temperature. A diffusion coefficient of  $10^{-2} \text{ cm}^2 \text{ s}^{-1(25)}$  which is estimated for Cr atoms from a surface analysis of a ferro-Cr alloy undergoing dissolution in a 0.1 M solution of hydrochloric acid, is several orders of magnitude higher than the diffusion coefficients required for volume–bulk diffusion, and proves that the observed redistribution rates in cathodically modified alloys can be accounted for by a surface-diffusion mechanism.

It therefore seems that the most important results of noble metal additions to Cr, stainless steel, and other alloys are:

- a. Cathodic modification can increase the corrosion resistance of materials in nonoxidizing acids by increasing the potential to a value that is in the passive potential range.
- b. During anodic dissolution, noble-metal atoms are redistributed on the surface of the alloy, probably by a surface-diffusion mechanism.

### 3.22.7 Cathodic Modification of Cr and Cr-Based Alloys

Since 1948, both Tomashov *et al.*<sup>6</sup> and Stern *et al.*<sup>8</sup> have proved that the tendency to passivation and the corrosion resistance of Cr in a nonoxidizing acid environment can be increased by the addition of small amounts of PGMs to these alloys.<sup>6,8,11,26–30</sup> Alloying with these cathodic additives causes dramatic improvements in corrosion resistance, and does not reduce the low-temperature plasticity of the Cr. It therefore opens up extensive possibilities for the use of these alloys in new industrial applications.

#### 3.22.7.1 Effect of the Addition of Noble Metals

##### 3.22.7.1.1 Cathodic modification

Greene *et al.*<sup>11</sup> conducted a comprehensive investigation into the influence of small additions of various PGMs, as well as some other noble metals, on the corrosion resistance of Cr in both nonoxidizing acids (hydrochloric, sulfuric) and an oxidizing acid (nitric). The tests carried out for the determination of the loss in mass in boiling sulfuric acid (5–98%), in hydrochloric acid (5–15%), and in nitric acid (65%) showed that an addition of as little as 0.1% PGMs to Cr (Cr–0.1% Pt) could cause a decrease in the corrosion rate of the Cr by a factor  $10^5$  or more. Each of the alloying additions improved the corrosion resistance in nonoxidizing environments, whereas several of the PGMs, particularly Pt and Ru, actually accelerated corrosion in nitric acid, which is a highly oxidizing environment. This phenomenon can be explained by the fact that the corrosion potential of Cr in a boiling solution of 65% nitric acid is very noble, and is very close to the beginning of its transpassive region. Alloying with an inert element having a large exchange-current density for the reduction of nitric acid can shift the existing high positive potential of the alloy into the transpassive region, resulting in an increased dissolution of the metal.

In electrochemical tests carried out at room temperature, a decrease in the critical anodic current density for passivation was found in all the Cr alloys containing noble elements, except those containing rhenium, silver and gold. The decreasing order of effectiveness of the various alloying additions in causing corrosion resistance in sulfuric and hydrochloric acids is as follows:

This can be correlated with the hydrogen-overvoltage behavior of these elements.

The corrosion of ductile Cr alloyed with Ru, osmium, iridium, Pt, Pd, and rhenium in solutions of 5–60% sulfuric acid at various temperatures has been described by Tomashov *et al.* in various papers.<sup>27–30</sup> Tomashov<sup>3</sup> found that Cr that has no cathodic additives (PGMs) corrodes at a high rate, while cathodically modified alloys self-passivate easily, and their corrosion resistance is several orders of magnitude higher than that of pure Cr. An increase in the concentration of the alloying component also increases the stability of the passive state.

A detailed study of Cr–Pd (0.1–0.4%) and Cr–Pt (0.1–0.4%) alloys in a 50% solution of sulfuric acid at 98°C<sup>30</sup> revealed that the addition of small amounts of nitrate ions (0.02%  $\text{NO}_3^-$  or 0.2 g dm<sup>−3</sup>  $\text{NO}_3^-$ ), which serve as an oxidizing agent, considerably increased the stability of the passive state in this aggressive condition. On the other hand, concentrations of up to 10 mg dm<sup>−3</sup> of chloride ions in solutions of 40% sulfuric acid at 65°C delayed the onset of self-passivation, and also narrowed the range of the passivation region for ductile Cr–0.3% Ru, and Cr–0.4% Ru alloys.<sup>6</sup> Work by Kato and Sakaki<sup>31</sup> on Cr with Pd and Ru additions, confirmed the beneficial effect of both on the increased corrosion resistance of the Cr in sulfuric acid, as well as the fact that Ru is more effective than Pd in this regard.

##### 3.22.7.1.2 Kinetic effect

Tomashov *et al.*<sup>27,29,32,33</sup> investigated the effect of PGMs on the active dissolution of ductile Cr in sulfuric acid. Results of the dissolution kinetics of ductile Cr alloyed with Ru, iridium, Pd, and Pt (0.1–0.4%) in a solution of 40% sulfuric acid at 65°C and at a fixed potential of −175 mV (SHE) show that the PGM alloying elements decrease the anodic dissolution rate of Cr, and also that the corrosion resistance of the alloy depends on the concentration and nature of the alloying addition.

Investigations of the Cr-PGM alloys by electron microscopy after active corrosion had taken place showed that the accumulating PGMs formed separate islets rather than a homogeneous layer on the surface of the alloy. It is presumed that the dissolution of Cr from the Cr-PGM alloy occurs by means of successive transfer into the solution of the atoms that are at the corners and edges of the crystal lattice and those that have an enhanced activity. If these sectors of the crystal lattice are blocked by more corrosion-resistant PGM atoms, anodic dissolution of the Cr atoms that lie on the flat steps of the alloy lattice and that bind more firmly to it will take place less readily. The PGM atoms gradually lose their bonding with the neighboring Cr atoms, and remain on the surface in the form of adsorbed atoms or adatoms.<sup>32-34</sup> The further surface diffusion of such adatoms results in the formation of microcrystals of pure PGMs, which are metals that preserve the electric contact with the substrate alloy.<sup>32,33</sup> Thus, with an increase in the PGM content of the alloy, more active surface centers are blocked by the added PGM atoms, and the rate of Cr solution from the alloy in the active state decreases. While Tomashov *et al.*<sup>32-34</sup> do not preclude the possibility of the partial solvation of the PGM atoms, they conclude that the changing distribution of the PGM metal occurs mainly as a result of a surface diffusion mechanism.

The retardation of the anodic dissolution of Cr by all the PGM additives seems to occur as a result of the operation of two mechanisms. The dominant mechanism is a blocking mechanism, in which the PGMs (as adatoms) block the active sites in the crystal lattice of Cr, thus preventing corrosion as described earlier. A lesser effect was also observed to occur as a result of a 'screening' mechanism, in which a layer of the PGM adatoms and trapped hydrogen in the pores between the cathodic component particles partly screen the surface of the alloy, causing a decrease in the active anodic surface and in corrosion.

### 3.22.8 Cathodic Modification of Stainless Steels

#### 3.22.8.1 Addition of Noble Metals to Fe-Cr Stainless Steels

The Tomashov group has made the main contribution to the knowledge of corrosion resistance of Fe-Cr alloys cathodically modified with noble metals in various acid media at different concentrations and temperatures.

In the 1960s, Tomashov<sup>35</sup> demonstrated the beneficial effect of the addition of Pt, Pd, rhenium, and copper to Fe-27% Cr alloys in 20–30% sulfuric acid at between 10 and 25 °C. Even small additions (less than 0.5%) of Pt, Pd, and rhenium reduced the corrosion in the Fe-27% Cr alloy by as much as 99.85%.<sup>17</sup> With its higher hydrogen overvoltage, copper is less effective as a cathodic additive. The addition of 0.2% Pd to Fe-18% Cr in 20% sulfuric acid of 20 °C resulted in a large increase in the corrosion resistance of the Fe-Cr alloy. Under these conditions, the corrosion resistance of Fe-18% Cr-0.2% Pd is comparable with that of an Fe-18% Cr-3% Mo alloy. When 0.2% Pd was added to Fe-25% Cr in 30% sulfuric acid at 20 °C, the alloy became even more corrosion resistant than Fe-25% Cr steels with additions of either 3% molybdenum or 6% nickel. The higher corrosion resistance of an Fe-18% Cr-3% Mo-0.2% Pd steel when compared to that of Fe-18% Cr-0.2% Pd and Fe-18% Cr-3% Mo steels illustrated, for the first time, the synergistic beneficial effect of the simultaneous additions of molybdenum and Pd to an alloy. This effect was later confirmed by Bieffer<sup>36</sup> and Higginson.<sup>18</sup>

After demonstrating the cathodic modification effect in Fe-Cr stainless steels, the Tomashov group discovered that the effect of cathodic additions was enhanced with an increasing Cr content (above 25%) in an alloy.<sup>37</sup> Investigations carried out on Fe-Cr alloys with varying Cr contents (25–100%) to which 0.2% Pd was added indicated that Fe-40% Cr-0.2% Pd had the optimum passivation characteristics in 10–50% sulfuric acid and 1% hydrochloric acid at 100 °C. Under these conditions, the Fe-40% Cr-0.2% Pd alloy required the minimum time for self-passivation and displayed the minimum corrosion in the passive range, as well as a small critical current density and a highly negative passivation potential. The addition of 0.2% Pd to the Fe-40% Cr steel caused a dramatic decrease of a factor of  $2 \times 10^5$  in the corrosion rate in a boiling solution of 40% sulfuric acid. The remarkable corrosion resistance of the Fe-40% Cr-0.2% Pd alloy when compared to that of other alloys can be clearly seen from Table 1.

Although the effect of the addition of Pd in improving the corrosion resistance is much less in hydrochloric acid, the corrosion rate in the passive state is still reduced by a factor of  $\sim 100$ . The alloy was found to have high corrosion rates in a solution of hydrochloric acid at concentrations of more than 1%.

This extraordinary corrosion resistance in sulfuric acid was confirmed by Higginson,<sup>18</sup> who found that

**Table 1** Corrosion rate (CR) of some acid-resistant alloys in 40% sulfuric acid at 100 °C

Alloy	CR (mm year <sup>-1</sup> )
Fe-40% Cr	~10 000 <sup>37</sup> ; ~5 000 <sup>38</sup> (10% acid)
Fe-23% Cr-28% Ni-3% Mo	3 <sup>37</sup>
Hastelloy A, B	0.2 <sup>37</sup>
C	0.3 <sup>37</sup>
Ti-30% Mo	0.18 <sup>37</sup>
Fe-40% Cr-0.2% Pd	0.05 <sup>37</sup>
Fe-40% Cr-0.2% Ru	0.03 <sup>38</sup>
Fe-29% Cr-4% Mo-2% Ni	~ 8000 <sup>39</sup>
Fe-29% Cr-4% Mo-2% Ni-0.2% Ru	12.93 <sup>39</sup>

an improvement was obtained in the corrosion rate of a factor of  $(1-5) \times 10^4$  for Fe-40% Cr-0.2% Pd and Fe-40% Cr-0.2% Ru alloys compared to that of Fe-40% Cr in a boiling solution of 10% sulfuric acid. The alloy containing Ru was more resistant than the alloy containing Pd. The greater effect of the Ru was explained on the basis that it is a more effective cathode for the evolution of hydrogen than is Pd. A similar investigation conducted by Howarth<sup>40</sup> indicated that no improvement in corrosion resistance is gained by the use of Pt rather than Ru for purposes of cathodic modification. Higginson<sup>18</sup> also observed that the critical time and charge density for spontaneous passivation of Fe-40% Cr-Ru alloys depends on the concentration of Ru in the alloy, and the kind of acid (hydrochloric or sulfuric) in which the corrosion takes place.

Work by Potgieter and van Bennekom<sup>41</sup> indicated that although the optimum Cr concentration for maximum corrosion resistance in Fe-Cr-0.2% Pd alloys was 40% Cr, there was no difference in the corrosion resistance of an Fe-40% Cr-0.2% Ru and an Fe-30% Cr-0.2% Ru alloy. This implies that in Ru containing alloys, the maximum Cr content can be restricted to 30% by mass, which means that it can be produced commercially in the same way as the patented Fe-28Cr-4% Mo superferritic stainless steel. It also means huge gains in the physical and mechanical properties of the alloy, as Fe-40% Cr alloys are very brittle and difficult to form. A later work by Wolff *et al.*<sup>42</sup> indicated that further additions of 5% Al to Fe-35/40% Cr-0.2% Ru not only improved the high temperature hot corrosion resistance at elevated temperatures, but also aqueous corrosion resistance against sulfuric acid solutions of 10% at room temperature. The Fe-40% Cr and

Fe-35% Cr-5% Al alloys corroded actively in 10% sulfuric acid, while the alloys containing 0.2% Ru additions passivate spontaneously, with the one containing the Al having the lowest corrosion rate. However, this latter alloy of Fe-35% Cr-5% Al had inferior pitting corrosion resistance compared to the Fe-40% Cr one in a 3.5% NaCl solution. Once again it was observed that the addition of 0.2% Ru to both the alloys increased their pitting resistance in the salt solution.

Detailed investigations were carried out by Tomashov<sup>43</sup> on Fe-25% Cr steels alloyed with 0.3% and 2.0% Pd and Ru in 5–50% sulfuric acid and 1 and 5% hydrochloric acid at 50–100 °C. It was found that the general and pitting corrosion resistance was higher in the alloys containing Ru than in the alloys containing Pd.

These results were attributed to several factors:

- Ru reduces the overvoltage of cathodic hydrogen generation more effectively than does Pd, thereby increasing the efficiency of the cathodic process.
- Ru, unlike Pd, reduces the rate of anodic dissolution by reducing the critical current density required for passivation, especially in media containing chloride ions. This observation was confirmed by both Bieffer<sup>36</sup> and Higginson.<sup>18</sup>
- Ru is susceptible to the adsorption of oxygen and the formation of phase oxides, and thus enters the composition of the hydroxide and oxide layers formed on the surface of the steel, while Pd remains as a separate metallic phase in the surface layer.
- Because the passivating oxide layers on the steel contain Ru as well as Cr, the resistance of the steel to the activating effect of chloride ions increases. Thus, Ru does not impair the resistance to pitting corrosion, but Pd does impair this resistance.

An electron microscopy investigation<sup>23</sup> into the accumulation of Pd on the surface of Fe-25% Cr-(0.1–0.5%) Pd in 10% sulfuric acid at 25–100 °C revealed that the size and amount of accumulated particles on the surface of the alloy depend not only on the initial concentration of the Pd in the alloy, but also on the temperature at which active dissolution takes place. The size and distribution of the accumulated Pd particles are explained on the basis of the theory of Erdey-Gruz and Volmer, which states that nuclei of crystallization arise at a definite supersaturation of adsorbed atoms on the surface of the alloy. An increase in the concentration of the Pd should therefore result in both an increase in the number of nuclei

and decrease in the particle size. Higginson<sup>18</sup> confirmed this in a study of the accumulation of Ru on Fe–40% Cr–(0.1–0.2%) Ru alloys corroding in 0.5 M sulfuric acid (4.9%) and 0.5 M hydrochloric acid (1.8%). He also found that a greater amount of accumulation occurred in a solution of hydrochloric acid than in sulfuric acid, apparently as a result of the adsorption of chloride ions, which increases the surface diffusion rate of Ru atoms during anodic dissolution.

Tjong<sup>44</sup> investigated the corrosion behavior of an Fe–24% Cr alloy with sputter-deposited Pd thin films on the surface in 0.5 M HCl solutions at room temperature, and found that prolonged corrosion protection against active dissolution in the hydrochloric acid medium is due to the formation of a sufficiently thick Pd-enriched surface layer containing Fe–Cr. Auger analysis of the passive surface revealed that a thick Cr oxide layer forms with and on the Pd-enriched surface, thus confirming the earlier work by Tomashov described above.<sup>3,23</sup> Recent work by Tjong and Chu<sup>45</sup> investigated the same parent alloy, but this time with Ru ion implanted on the surface, and in sulfuric acid. They found that the basic alloy with Ru does not passivate in the 0.5-M sulfuric acid solution, whereas the one containing ion-implanted Ru atoms does. Furthermore, XPS analysis of the passivated surface showed that Ru is incorporated as Ru<sup>4+</sup> species in the hydrated Cr oxyhydroxide passive film formed on the Ru-implanted Fe–24% Cr alloy, which is once again in agreement with the results from Tomashov<sup>3</sup> discussed above.

Bieffer<sup>36</sup> assessed the influence of several transition metals, as well as additions of Pd and rhenium in different concentrations to type 430 ferritic stainless steel (17% Cr) in 0.5-M sulfuric acid at ambient temperature (24 °C). The results indicate that the addition of 0.46% Pd to 430 stainless steel resulted in spontaneous passivation, but insufficient levels of Pd (0.06–0.26%) increased the active corrosion rate by a factor of as high as 10.

It was found that in 1-M hydrochloric acid (3.6%), the additions of Pd to steel 430 were strongly deleterious, and increased the corrosion rate from a factor of 10 to a factor of 30. Further, it was observed that Pd was deleterious to the pitting corrosion of ferritic stainless steels. However, at levels of 0.99% Pd, 430 stainless steel appears to have a superior corrosion resistance even to that of highly alloyed austenitic stainless steels in concentrated sulfuric acid at high temperatures.

Although Tomashov<sup>35</sup> concluded that the addition of 0.2% Pd to Fe–18% Cr steel was sufficient to result in spontaneous passivation in 20% sulfuric acid at 20 °C, Bieffer<sup>36</sup> found that type 430 stainless steel with an addition of 0.26% Pd did not passivate spontaneously in 0.5 M sulfuric acid at 24 °C. A probable reason for this discrepancy is the presence of relatively high amounts of carbon and impurities in the 430 stainless steel. Lizlovs and Bond<sup>46</sup> showed, in measurements of anodic polarization, that the performance of a standard type-430 steel was surpassed by that of a 17% Cr steel of high purity.

### 3.22.8.2 Addition of Noble Metals to Fe–Cr–Mo Stainless Steels

Tomashov *et al.*<sup>47–49</sup> investigated the corrosion characteristics of several Fe–Cr stainless steels containing molybdenum (2–3%) and Pd (0.1–0.5%) in sulfuric acid (1–80%) at temperatures varying from 10 °C to boiling point (about 100 °C). The results indicated that, when molybdenum is added to an Fe–25% Cr steel containing 0.3% Pd, the concentration and temperature ranges in which the steels self-passivate in sulfuric acid are narrowed.

According to them, the simultaneous alloying of Fe–24% Cr with molybdenum and Pd leads to a marked increase in the stability of the passive film in sulfuric acid, because molybdenum is incorporated in the passivating film on the steel, resulting in a more protective surface layer.<sup>48</sup> The shrinkage of the region of passive behavior was also confirmed by Agarwala and Bieffer<sup>50</sup> in their investigation of type-430 stainless steel, especially at high concentrations of sulfuric acid. They found that type-430 steels with additions of 3% Mo–0.5% Pd and 2% Mo–1% Pd had comparatively large regions of spontaneous passivity in sulfuric acid up to concentrations of 25% at temperatures near boiling point. They even passivated in the presence of 2–3% sodium chloride in sulfuric acid solutions at 24 °C, thus showing much more resistance to chlorides than steels that contain only Pd.

The Tomashov group<sup>49</sup> showed further that Fe–18% Cr–2% Mo alloyed with 0.3% Pd self-passivates, is corrosion resistant in 1–40% sulfuric acid at between 10 and 100 °C and has a lower corrosion rate than commercial Fe–18% Cr–10% Ni stainless steel under the same conditions.

Streicher<sup>17,51</sup> also investigated the effect of additions of PGMs to an Fe–Cr–Mo alloy. Without these additions, the rate of attack on an Fe–28.5%Cr–4% Mo alloy in a 10% solution of boiling sulfuric acid

was found to be  $\sim 52\,000\text{ mm year}^{-1}$ . Each of the six added PGMs, when present in excess of a certain minimum amount that varied from 0.005 to 0.2%, passivated the Fe–28.5% Cr–4% Mo alloy in 10% boiling sulfuric acid. The minimum concentration of PGMs required to passivate the base alloy decreased with an increase in the Cr content. Additions of a PGM at a concentration lower than the required to produce passivity actually increased the corrosion rate as compared to that of Fe–28.5% Cr–4% Mo. This was also observed by Bieffer<sup>36</sup> for Fe–17% Cr (type 430 steel). Scheers *et al.*<sup>52</sup> and McEwan *et al.*<sup>53</sup> found that Fe–29% Cr–4% Mo–2% Ni with small amounts of Ru also performed excellently in phosphoric acid solutions, and that Ru greatly enhances the corrosion resistance of the base alloy. Further work by Potgieter *et al.*<sup>39</sup> on these Fe–29% Cr–4% Mo–2% Ni alloys with various levels of Ru and silver additions, as well as a partial copper substitution for Ni, confirmed that excellent corrosion resistance can be achieved against sulfuric acid solutions as concentrated as 30–40% at boiling point with decreases in corrosion rates by a factor of  $10^2$  to  $10^3$ . A level of at least 0.2% Ru is required for a worthwhile and significant corrosion resistance improvement, and silver additions, even in much larger concentrations than Ru, are not as effective as Ru to improve corrosion resistance of the base alloy. Substitution of half of the Ni with a similar amount of Cu does not seem to have a major beneficial or detrimental effect, except in severely aggressive conditions (40%  $\text{H}_2\text{SO}_4$  at boiling point), where the effect is decidedly detrimental. This is shown in **Table 2**, which also includes a value of a duplex stainless steel discussed further on in this report.

The observation made by both Tomashov *et al.*<sup>48</sup> and Agarwala and Bieffer<sup>50</sup> that the simultaneous

presence of Pd and molybdenum in Fe–Cr steels promotes more stable passivity than the presence of each individual element alone was confirmed by both Streicher<sup>17,51</sup> and Higginson.<sup>18</sup> Higginson found that Fe–40% Cr that had been alloyed with both 1.8% molybdenum and 0.1% Ru passivated far more quickly in sulfuric acid (0.5 M) than did an Fe–40% Cr–0.1% Ru alloy. According to Tomashov *et al.*<sup>48</sup> this is true not only for solutions of sulfuric acid, but also for solutions of dilute hydrochloric acid (1–3%). However, Higginson<sup>18</sup> showed that the addition of 0.1% Ru to an Fe–40% Cr–1.8% Mo steel could not cause the spontaneous passivation of the alloy to occur in a solution of 0.5 M hydrochloric acid. The fact that Tomashov *et al.*<sup>48</sup> could achieve spontaneous passivation while Higginson could not, can be attributed to different conditions in their respective investigations.

The addition of molybdenum has different effects on the corrosion resistance of Cr steels in the active state in solutions of sulfuric and hydrochloric acid. In solutions of sulfuric acid, the presence of molybdenum reduces the corrosion rate, but in solutions of hydrochloric acid, it increases the rate. The corrosion potential in both acids of steel containing molybdenum is more positive than that of steel without molybdenum. This fact can be explained if it is assumed that molybdenum not only retards anodic dissolution, but also increases the effectiveness of the cathode process owing to the reduced overvoltage of hydrogen on molybdenum. The predominant action of molybdenum on the anodic process appears in solutions of sulfuric acid but, in hydrochloric acid, where passivation is hindered by the presence of chloride ions, it is mainly the cathodic influence of molybdenum that prevails. This leads to a marked increase in the rate of dissolution of steel, because the

**Table 2** Corrosion roles of a superferritic SS with various Ru and Ag additives in boiling sulfuric acid solutions

Alloy	$[\text{H}_2\text{SO}_4]$ %			
	10	20	30	40

Fe–29% Cr–3% Mo–14% Ni–0.20% Ru	0.000			
Fe–29% Cr–4% Mo–2% Ni–0.1% Ag	0.0227	3.719		
Fe–29% Cr–4% Mo–2% Ni–0.5% Ag	0.0333	1.560		
Fe–29% Cr–4% Mo–2% Ni–1.0% Ag	0.1183	0.4726		

effectiveness of the cathodic process on molybdenum in hydrochloric acid is insufficient to bring the steel into the passivated state. The simultaneous presence of Pd and molybdenum in steel produces a more effective cathodic process<sup>48</sup> and could possibly lead to passivation. Thus, in sulfuric acid molybdenum affects not only the cathodic process (together with PGMs), but also retards the anodic process. The combined influence of molybdenum and PGMs on the anodic and cathodic processes of Fe–Cr stainless steel in sulfuric acid is summarized schematically in **Figure 4**.

Streicher<sup>51</sup> also carried out investigations into the pitting corrosion of Fe–28% Cr–4% Mo alloys to which PGMs in several halide media had been added.

The results show clearly that Pd destroys the pitting resistance in all of the three pitting solutions tests, while rhodium impairs the resistance in ferric chloride and the bromine–bromide solution. None of the other four PGMs had any influence on the pitting resistance in these media, except for Pt, which caused failure in the bromine–bromide solution. No mechanism was suggested as an explanation for these observations. Streicher concluded that, of the six PGMs only iridium, osmium, and Ru can be used to produce the passivity of stainless steels in sulfuric acid without impairing their resistance to pitting corrosion in oxidizing chloride and bromide environments. Recent

investigations by Sherif El-Sayed *et al.*<sup>54</sup> on the behavior of Fe–Cr–Ni–Mo–(0–0.3% Ru) in chloride media confirmed the beneficial effect of Ru on the pitting corrosion resistance of stainless steels.

As far as organic media are concerned, it was found<sup>35</sup> that the addition of 0.1% Pd to Fe–25% Cr in a solution of 50% formic acid at 100 °C decreased the corrosion rate of steel by a factor of approximately 60. An Fe–25% Cr–3% Mo steel is stable under these conditions, both with and without Pd.

### 3.22.9 Cathodic Modification of Fe–Cr–Ni Stainless Steels

Although the effect of cathodic alloying additives on Fe–Cr–Ni stainless steels is not as dramatic as for Fe–Cr steels, it can nevertheless bring about marked improvement in the corrosion resistance of Fe–Cr–Ni alloys, especially in fairly aggressive conditions.<sup>55</sup>

#### 3.22.9.1 Addition of Noble Metals to Fe–Cr–Ni Stainless Steels

The addition of 0.1–0.5% Pt, 0.1–0.9% Pd and 1.2% Cu to Fe–18% Cr–9% Ni (an austenitic stainless steel) in 20–40% sulfuric acid at 20 °C reduced the corrosion of the Fe–Cr–Ni alloy by as much as 99.85%.<sup>17,56</sup> The results also indicated that the effectiveness of the alloying additions increased in the order Cu < Pd < Pt.

An electrochemical investigation into the alloying of Fe–25% Cr–6% Ni steel with Pd<sup>57</sup> (0.1%, 0.2%, and 0.5%) showed that the corrosion rate is reduced by more than an order of magnitude in 20% sulfuric acid at 100 °C over that for steel without Pd. However, steels containing Pd (0.1–0.5%) do not reach the stable passive region, and continue to dissolve at a considerable rate. The corrosion rate of Fe–25% Cr–6% Ni–0.5% Pd in a solution of 10% sulfuric acid at 100 °C is lower by a factor of 4 compared with the steel without any Pd.

Tomashov<sup>35</sup> also demonstrated that the addition of 0.2% Pd to an Fe–18% Cr–10% Ni alloy greatly reduced the corrosion of this austenitic stainless steel. The substitution of part of the nickel by manganese (Fe–18% Cr–2% Ni–8% Mn) produced an austenitic stainless steel with a corrosion performance that was not nearly as good as that of a steel with 10% nickel. The alloying of this manganese substituted steel with 0.2% Pd rectified this impaired corrosion resistance, and resulted in a steel with similar

**Figure 4** Summary of the effects of alloying additions on the polarization characteristics of Fe–Cr stainless steel in sulfuric acid.

corrosion characteristics to that of an Fe–18% Cr–10% Ni–0.2% Pd alloy.

A recent study by Peled and Itzhak<sup>58</sup> into the effect of silver, Pd, and gold on the corrosion behavior of hot-pressed and sintered type 316 stainless steel in 0.5-M sulfuric acid at 25 °C indicated that the corrosion resistance of the base alloy could be dramatically improved by additions of noble metals. Silver concentrations of less than or equal to 1% improved the corrosion resistance of the sintered stainless steel only for limited periods of exposure. Pt additions of about 2% were found to be sufficient to preserve the sintered stainless steel in the passive state. However, high Pt contents (about 5%) resulted in a tendency for the passive layer to break down. Samples containing additions of gold at various concentrations (1–5%) exhibited clear anodic active-passive transitions with a wide range of passivation. The addition of 5% gold to the sintered stainless steel caused the alloy to remain passive.

An interesting beneficial synergistic effect between nickel and Ru was noticed by Streicher.<sup>51</sup> Lower concentrations of Ru (0.1%) and nickel (0.1%) were needed to passivate Fe–28% Cr–4% Mo in a 10% solution of boiling sulfuric acid than the concentrations of either Ru (0.2%) or nickel (0.25%) that were needed when they were used alone. Although it seemed that Higginson<sup>18</sup> was unaware of that since he neither confirmed nor disproved it; he nonetheless found that the addition of 1% nickel to a Fe–40% Cr–0.1% Ru alloy resulted in an increase in the time needed for the occurrence of spontaneous passivation in 0.5 M sulfuric acid. He also concluded that the inhibition of the anodic dissolution reaction in sulfuric acid was much greater for the alloy containing both nickel and Ru than for that containing only 0.1% Ru. The alloying of Fe–40% Cr–0.1% Ru with 1% nickel also caused spontaneous passivation to occur approximately seven times faster in 0.5 M hydrochloric acid than for the Fe–40% Cr–0.1% Ru alloy. Thus, while an addition of 1% nickel to Fe–40% Cr–0.1% Ru was advantageous and lowered the passivation time in hydrochloric acid, the same did not apply when sulfuric acid was used since the passivation time increased. This synergistic effect between Ni and Ru was also confirmed by Potgieter and Kincer<sup>38</sup> in sulfuric acid, in their work on Fe–40% Cr–Ni–Ru alloys in 0.5 M hydrochloric and sulfuric acids. Their results indicated that less expensive Ni can be substituted for Ru to improve corrosion resistance effectively in sulfuric acid, but not in hydrochloric acid.

As far as organic acid media are concerned, work by the Tomashov group<sup>35,55</sup> indicated that an Fe–25% Cr–6% Ni–0.1% Pd alloy in a solution of 50% formic acid at 100 °C had a significantly reduced rate of corrosion when compared with the alloy without Pd. An alloy of 26% Cr–0.5% Ni to which noble metals had been added (0.5% Pt and 0.5–1.0% Pd) could withstand solutions of 50% formic acid and 10% oxalic acid at 100 °C for better than a similar alloy without the additions of any noble metals.

### 3.22.9.2 Addition of Noble Metals to Fe–Cr–Ni–Mo and Fe–Cr–Mn–Ni Stainless Steels

Investigations by Tomashov *et al.*<sup>35,55,59,60</sup> into the corrosion resistance of nitrided stainless steels revealed that an addition of 3% molybdenum to Fe–25% Cr–6% Ni steel in a solution of 30% sulfuric acid at 20 °C produced a sufficiently stable alloy in which the further addition of Pd (0.1%) did not result in any significant improvement in the corrosion resistance.<sup>55</sup> This occurs as a result of the fact that molybdenum not only retards the anodic dissolution of steel, but also promotes the cathodic evolution of hydrogen. Passivation is thus caused by the increased effectiveness of the cathodic process as well as the inhibition of the anodic process.

The work of the Tomashov group also showed that highly nitrided (0.7–0.9%) Fe–25% Cr–3% Ni–2% Mo–Mn stainless steels to which 0.1–0.5% Pd had been added had a very high corrosion resistance in mildly aggressive conditions, such as in solutions of 20–40% sulfuric acid at 20–100 °C, as well as in solutions of 1–3% hydrochloric acid at 20–50 °C.<sup>59</sup> However, at least 0.2% Pd is needed for self-passivation and high corrosion resistance to occur under more aggressive conditions (2% or higher hydrochloric acid at 50 °C or higher and 30% or more sulfuric acid at 50 °C or higher).<sup>55</sup> In mildly aggressive media, the corrosion resistance of the steel depends on the ability of the molybdenum to cause self-passivation as a result of the increased effectiveness of the cathodic process and inhibition of the anodic process. The simultaneous addition of Pd and molybdenum in a stainless steel broadens the region of self-passivation of the steel. The favorable influence of Pd on the corrosion resistance of stainless steel is due primarily to the cathodic modification of the steel and, in the presence of molybdenum, to its beneficial effect on the stability of the passive state.

Results also indicated that Fe–25% Cr–6% Ni–3% Mo–0.2% Pd that does not contain nitrogen could not be passivated in a solution of hydrochloric acid. Only a high nitrogen content (0.5% or more) leads to an increase in the corrosion resistance and self-passivation of these alloys in solutions of dilute hydrochloric acid (2–5% hydrochloric acid at 50 °C).<sup>60</sup> The positive influence of nitrogen occurs as a result of its influence on the structure of steel. A high nitrogen content creates a more homogeneous austenitic structure, and thus prevents the partitioning of Cr, molybdenum, and nickel in a two-phase austenitic–ferritic structure. Steel containing Pd but no nitrogen cannot be passivated in solutions of hydrochloric acid, apparently owing to the heterogeneity of the structure, which contains ~40% ferrite. The presence of appreciable amounts of both austenite and ferrite phases in the alloy, which cause a galvanic interaction between the two electrochemically different phases, is possibly responsible for this observed corrosion behavior.

Work carried out by Tjong<sup>61</sup> on Fe–24Cr–6V–Ru (0–0.2%) and Potgieter<sup>62</sup> on Fe–22% Cr–5% Ni–3% Mo–(0–0.3%)Ru and having a very low nitrogen content, showed that in these ferritic steels Ru has a major beneficial effect in increasing the corrosion resistance of the base alloy towards attack by 1 M H<sub>2</sub>SO<sub>4</sub> solutions. The effect increases by increasing the Ru contents, and the Ru in all cases caused a shift in the open-circuit corrosion potential towards more noble values. Under conditions of active–passive transition behavior, Ru additions also lowered the critical current density required for passivation and lowered the cathodic Tafel slope.

Tomashov *et al.*<sup>59</sup> proved that Fe–Cr–Ni–Mn and Fe–Cr–Mn alloys containing 0.5% Pd self-passivated, and had a high corrosion resistance in solutions of 20% sulfuric acid at 100 °C. However the steels containing only 0.2% Pd did not self-passivate in solutions of 2 and 3% hydrochloric acid at 25 °C, and had a low resistance to corrosion. Manganese shifts the complete passivation potential of Fe–Cr steel to values that are more positive, but to a lesser degree than nickel. The beneficial effect obtained when Cr steels are alloyed with nickel and manganese can be ascribed to the fact that they cause a smaller shift in potential to the positive direction upon complete passivation than occurs when they are alloyed with nickel alone. The further addition of nickel to Cr–Mn steels also lowers the critical current density at the onset of passivation. This permits better self-passivation, and a higher corrosion resistance upon cathodic alloying.

### 3.22.9.3 Galvanic Coupling in Fe–Cr–Ni Stainless Steels

Bianchi *et al.*<sup>63</sup> investigated the galvanic coupling of different stainless steels with sheet Pt in various non-oxidizing acid solutions at various concentrations and temperatures. For example, it was found that, in an aerated solution of 38% sulfuric acid at 25 °C, types 316, 304, and 430 (a ferritic alloy) stainless steel resisted corrosion when the ratio of the area of Pt to that of the stainless steel was 1, 10, and 100, respectively. This acquired corrosion resistance was attributed to the anodic protection of the stainless steels by Pt, which is a more efficient cathode for the reduction of oxygen. This greater efficiency of Pt for the reduction of oxygen shifted the potential of the stainless steel to a value in the passive range, thereby enhancing the resistance to corrosion. The same effect is observed when Pt is alloyed with steel, and is known as a cathodic modification of the stainless steel by the PGM. The galvanic coupling of two austenitic stainless steels, AISI 304 (18% Cr–8% Ni) and AISI 316 (18% Cr–8% Ni–2% Mo) with Pt, was studied electrochemically by Kabi *et al.*<sup>64</sup> in solutions of 2 and 5 M sulfuric acid at 28 °C. They confirmed that galvanic coupling with Pt enhanced the corrosion resistance of both steels, since the critical current density was lowered at the onset of passivation, as was the passivating current density. The corrosion potential of both alloys also shifted to a more positive value.

### 3.22.10 Cathodic Modification of Duplex Stainless Steels

The development of the duplex stainless steels (steels containing a ferrite–austenite mixture) was first reported by Bain and Griffiths<sup>65</sup> as early as 1927. Duplex stainless steels combine the advantages of ferritic and austenitic stainless steels and, although a large amount of data has been collected and published about duplex stainless steels, very little work has been reported in the literature about the addition of noble metals to these steels.

It appears that Tomashov's is the only group that has carried out any work on the influence of the addition of noble metals on duplex stainless steels. Furthermore, it appears that their work on the addition of Pd to duplex stainless steels was purely incidental, their main thrust having been focused on the investigation of the effect of Pd on the corrosion characteristics of

highly nitrated austenitic stainless steel (some containing molybdenum as well) in non-oxidizing acid solutions. The occurrence of two phases (ferrite and austenite) in some highly nitrated austenitic stainless steels also led to investigations of duplex stainless steels that were alloyed with Pd.<sup>59</sup>

In one of the investigations by the Tomashov group<sup>60</sup> into the corrosion resistance of Fe–Cr–Ni stainless steels in hydrochloric acid, two duplex stainless steels were produced with low levels of nitrogen (0.03% or more). The Fe–25% Cr–6% Ni–3% Mo alloy contained 30% ferritic phase, while the Fe–25% Cr–6% Ni–3% Mo–0.2% Pd alloy contained 40% ferrite phase. Both steels were found to corrode actively in a solution of 3% hydrochloric acid at 50 °C.

A higher corrosion rate was found in the duplex steel containing Pd because, in conditions in which the steel does not self-passivate and in which it corrodes with the evolution of hydrogen, the presence of an effective cathodic additive with a low hydrogen over-voltage enhances the cathodic reaction and increases the corrosion rate.

This investigation showed that duplex stainless steels containing Pd cannot be passivated in a solution of up to 3% hydrochloric acid at 50 °C because of the heterogeneity of its structure. Both Cr and molybdenum are powerful ferrite stabilizers, while nickel is primarily an austenite stabilizer. Therefore, the distribution of the different components in the two phases differs by several percentage points as a result of partitioning. The austenitic phase, being depleted of Cr and molybdenum and enriched with nickel, experienced difficulty in achieving passivation.

In another paper on the corrosion resistance of highly nitrated austenitic stainless steels alloyed with Pd, Tomashov *et al.*<sup>59</sup> produced some duplex stainless steels that typically consisted of 18–25% Cr, 7–11% Mn, ~2% Mo, and nearly 1% N, with a varying ferrite content of 36–50%. These steels were additionally alloyed with 0.1–0.5% Pd. No nickel was present in any of these alloys.

Corrosion tests conducted in solutions of 20–50% sulfuric acid at 20–100 °C indicated that all the duplex alloys containing Pd initially corroded intensively after immersion and activation before they became self-passivated. The time required for self-passivation decreased with an increase in both the Pd content of the steel and an increase in temperature, but increased with an increase in the concentration of acid (20–40% sulfuric acid). In a solution of 20% sulfuric acid at 100 °C, only the steels containing

0.4% and 0.5% Pd self-passivated. This investigation also showed that duplex stainless steels containing Pd had a greater corrosion resistance in 2–3% hydrochloric acid at 20–50 °C than did similar cathodically modified austenitic stainless steels.

Potgieter<sup>66</sup> carried out an extensive investigation into the corrosion behavior of different stainless steel groups cathodically modified with Ru in sulfuric acid solutions at various temperatures. Three groups of low nitrogen duplex stainless steels were investigated, namely Fe–22% Cr–3% Mo, Fe–29% Cr–3% Mo, and Fe–35% Cr–3% Mo, with sufficient amounts of Ni added to each group (9.14% and 18% respectively) to ensure a fully duplex structure containing approximately equal amounts of austenite and ferrite in each case after suitable heat treatment. Varying amounts of Ru, namely 0.1–0.3%, were added to each of the base alloys in each group, yielding a total of twelve alloys. One of the reasons for the selection of the three groups was to determine whether the effect of the Ru in inhibiting corrosion would become more enhanced with an increasing Cr content in the alloy, as was the case with the ferritic and superferritic stainless steel. The choice of Ru was motivated by two factors, that is, the fact that it was more effective than Pd, and the huge excess being produced in South Africa for which there is currently no alternative applications. The compositions of the various alloys are given in **Table 3**.

The results obtained from mass loss tests indicated that significant decreases in the corrosion rates of duplex alloys could be obtained by the addition of small amounts of Ru to the base alloys. The increase in the corrosion resistance was the most

**Table 3** Chemical composition (%m/m) of the duplex stainless steels investigated

Alloy	Cr	Ni	Mo	Ru
377	22.0	9.07	2.81	–

For each alloy the balance of the composition is made up of Fe.

pronounced in the alloy group with the lowest Cr and nickel content. Electrochemical measurements indicated that the corrosion potentials of all the alloys containing Ru were raised to more noble values in sulfuric acid solutions. Under conditions where the alloys passivated spontaneously, a decrease in cathodic Tafel slopes occurred. When the alloys were actively corroding, Ru additions decreased the critical as well as the passive current densities of all three groups of alloys. Increasing acid concentrations and temperatures were found to increase the corrosion rates, critical current densities and passive current densities of all the alloys investigated. At the same time a lowering in the corrosion potential occurred for each individual alloy with increasing severity of the corrosive environment. In contrast to commercial duplex stainless steel, where the potential of the specimen with respect to the environment determines the phase that would preferentially corrode, only the ferrite phase corroded preferentially in these low nitrogen duplex alloys through a range of active to passive potentials investigated.

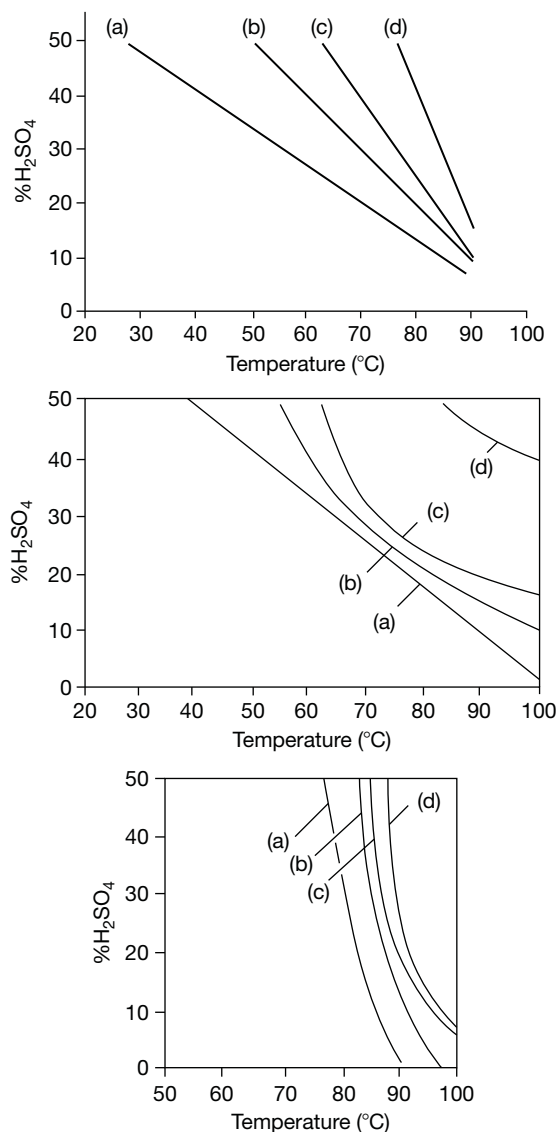

The effect of the various acid concentrations and temperatures used in the investigation on the different duplex stainless steel group can best be described by the compiled isocorrosion curves presented in Figure 5. Areas to the left and below each curve indicate the conditions where stable (spontaneous) passivation occurs, while areas to the right and above each curve indicate active corroding conditions. The beneficial effects of increased Cr and nickel additions in improving the corrosion resistance between each of the groups of duplex stainless steels are clearly visible, while the beneficial effect of increasing Ru additions in each group can also be easily distinguished.

### 3.22.11 Surface Alloying with PGMs

Unlike bulk alloying, which requires the introduction of a considerable amount of a noble-metal component to obtain a protective effect, surface alloying seems to be a more economical way to achieve the same purpose. It is therefore not surprising that a fair amount of research has been conducted to establish the corrosion resistance of various alloys with PGM surface coatings.

#### 3.22.11.1 Cathodically Modified Cr Coatings

Tomashov *et al.*<sup>67</sup> showed that the corrosion resistance of electrolytic Cr plating could be substantially

**Figure 5** Isocorrosion curves of different duplex stainless steel group with varying Ru concentrations (i) 22% Cr–9% Ni–3% Mo (a = 0% Ru; b = 0.1% Ru; c = 0.2% Ru; d = 0.3% Ru); (ii) 29% Cr–13% Ni–3% Mo (a = 0% Ru; b = 0.1% Ru; c = 0.2% Ru; d = 0.3% Ru); and (iii) 35% Cr–17% Ni–3% Mo (a = 0% Ru; b = 0.1% Ru; c = 0.2% Ru; d = 0.3% Ru).

increased in solutions of nonoxidizing acids when Cr and Pd were deposited layer by layer. Small additions of Pd (1–3%) significantly increased the corrosion resistance of Cr coatings in solutions of 20% sulfuric acid and 5–10% hydrochloric acid. The sequence of alternating Cr and Pd layers, as well as subsequent heat treatment (annealing) after plating, also influenced the corrosion characteristics.

### 3.22.11.2 Surface Alloying in Fe–Cr Alloys

When Fe–27% Cr is surface alloyed with Pd (0.1–0.5  $\mu\text{m}$ ) by an electroplated coating followed by annealing, it acquires a high resistance to corrosion in solutions of 20% sulfuric acid at 100 °C.<sup>68–70</sup> While steel that does not contain Pd was nonresistant, the corrosion rate in the coated steel decreased by several orders of magnitude. The annealing of the samples did not hinder the corrosion resistance, despite the diffusion of a considerable amount of Pd into the base metal. In milder conditions, the introduction of less Pd into the surface layer is even sufficient to prevent corrosion. It was calculated<sup>69</sup> that the minimum amount of Pd that is necessary per unit surface area to impart corrosion resistance is about 0.1 g m<sup>−2</sup>, which corresponds to mean Pd layer thickness of  $\sim 10$  nm.

The electrospark method of coating<sup>68–70</sup> yields similar results for corrosion resistance in Fe–27% Cr, and may offer a convenient method for increasing the corrosion resistance of large structures that cannot be electroplated with Pd in baths.

Agarwala and Bieffer<sup>50</sup> agree with the Tomashov group that the surface deposition of Pd appears to be a relatively inexpensive way of obtaining good corrosion resistance in stainless steels. They found that the deposition of Pd from a Pd chloride solution onto type 430 stainless steel and type 430 stainless steel plus 2% molybdenum cause the specimens to passivate spontaneously when exposed to 0.5-M sulfuric acid. The molybdenum-bearing steel was more readily passivated than the molybdenum-free steel. They concluded that this behavior supports statements that Pd enriched the surface of an alloy during the initial period of corrosion.

### 3.22.11.3 Surface Alloying Fe–Cr–Ni Stainless Steel

Work on the cathodic alloying of Fe–Cr–Ni stainless steel surfaces was first carried out by Bianchi *et al.*<sup>71</sup> who electroplated a Fe–19% Cr–11% Ni alloy with Pt. They concluded that, even with a Pt coverage of as low as 20 mg m<sup>−2</sup>, the Pt provides efficient protection of the stainless steel in solutions of concentration up to 75% H<sub>2</sub>SO<sub>4</sub> at 25 °C. They attributed this greater corrosion resistance of the stainless steel to two factors. First, Pt is a more efficient cathode for the reduction of oxygen than is stainless steel and, second, the selective deposition of Pt in the form of small round particles ( $\sim 0.01$   $\mu\text{m}$  in diameter) blocked the most active sites of the stainless steel surface. Electron microscopy was carried out on thin-film samples, and provided evidence for the selective

electrodeposition of Pt at emerging dislocations and grain boundaries.

Tomashov *et al.*<sup>68,72</sup> investigated this possibility using two different methods of applying Pd to the surface of an Fe–18% Cr–10% Ni alloy, namely electrolytic plating, and electrospark alloying. The Fe–18% Cr–10% Ni alloy with electrolytically deposited coatings of Pd (0.1–5  $\mu\text{m}$ ) acquire high corrosion resistance in a solution of 20% sulfuric acid at 100 °C. Under less aggressive conditions, even less Pd is required in the surface layer to protect the steel from corrosion. When the Fe–18% Cr–10% Ni stainless steel was modified by electrospark alloying, stable passivity was once again obtained. When an Fe–40% Cr–0.2% Pd alloy was used for the coating, the concentration of Pd on the surface of the Fe–18% Cr–10% Ni steel was  $\sim 1\%$ , which increased to between 12 and 18% as self-passivation was established. It was found that spark alloying with this combined Cr and Pd alloying addition produced better resistance against corrosion than that obtained when alloying was carried out with Pd alone. However, electrolytic deposition produced a smoother more continuous coating than was produced by spark alloying.

In acid solutions (20% H<sub>2</sub>SO<sub>4</sub> at 100 °C), the simultaneous presence of a specimen of carbon steel, which dissolves with the evolution of hydrogen, causes the potential of the specimen coated with Pd (1  $\mu\text{m}$ ) to shift towards a more negative value, and causes the stainless steel to dissolve actively. This situation arises irrespective of whether or not there is contact between the carbon steel and the stainless steel coated with Pd.

Potgieter and van Bennekom<sup>73</sup> investigated the corrosion behavior of 316 austenitic stainless steel electrolytically plated with silver and heat treated to diffuse the silver into the material in various sulfuric acid solutions at temperatures of 25, 45, and 75 °C. Table 4 gives an indication of the performance of the base and plated alloys in the various H<sub>2</sub>SO<sub>4</sub> solutions. As can be expected, the best corrosion resistance was observed in the solutions at 25 °C, while the most severe corrosion occurred in the solutions at 75 °C. The silver plated alloy by far outperformed the unplated base alloy under all test conditions, and caused a marked improvement in corrosion resistance. Furthermore, silver has the advantage that it is substantially cheaper than Ru, almost by a factor of 10.

Potgieter *et al.*<sup>74</sup> investigated the effect of Ru evaporated by an electron beam onto an Fe–22% Cr–9% Ni–3% Mo duplex stainless steel on the corrosion

**Table 4** Electrochemical parameters of surface alloyed and nonsurface alloyed 316 SS at 25 °C

$H_2SO_4$ (%)	Nonalloyed with Ag		Surface alloyed with Ag			
	$i_{crit}$ ( $A\ cm^{-2}$ )	$i_{corr}$ ( $A\ cm^{-2}$ )	$E_{corr}$ (mV)	$i_{crit}$ ( $A\ cm^{-2}$ )	$i_{corr}$ ( $A\ cm^{-2}$ )	$E_{corr}$ (mV)
1	37.1	12.84		21.1	6.18	
10		28.48	102		11.15	264
20	87.4	37.41	−310	42.6	13.43	285
30	99.6	90.91	−120	63.3	24.30	280

**Table 5** Main features of the influence of noble metal additions on the corrosion resistance of various alloy systems

Alloy system	$H_2SO_4$	HCl
Ductile chromium	5–98% at boiling point 0.1% PGM additions cause a decrease in the corrosion rate by a factor of $10^5$ or more Decreasing order of effectiveness of PGMs: Ir > Rh > Ru > Pt > Pd > Os.	5–15% at boiling point
Ferritic stainless steels	20–30% at 25 °C. Additions of <0.5% PGMs decrease the corrosion rate by as much as 99.85% Synergistic beneficial effect on corrosion rate if both a PGM and Mo are present in an alloy. Effect of PGM on corrosion rate increase with increasing chromium content (above 25% in an alloy). Fe–40% Cr–0.2% Pd even more resistant than Hastelloy alloys in 10–50% at boiling point	1% at boiling point
Austenitic stainless steels	Ru a better cathodic additive than Pd. Insufficient cathodic additive accelerates corrosion Behaviour of PGM alloyed ferritic SSs different in $H_2SO_4$ and HCl media. Effect of PGM additions not as dramatic as for ferritic stainless steels, but increase corrosion resistance nonetheless, especially in fairly aggressive conditions. Synergistic beneficial effect on corrosion rate if both a PGM and nickel are present in an alloy.	
Duplex stainless steel	Also possible to enhance corrosion resistance by galvanic coupling with Pt. 20–50% at 20–100 °C PGM additions (0.5%) cause self-passivation	3% at 50 °C. Alloys with low nitrogen content corrode actively even with PGM additions. 2–3% at 20–50 °C Highly nitrided manganese substituted duplex SSs with PGM additives more resistant than similar cathodically modified austenitic SS

resistance of the alloy in 10%  $H_2SO_4$ , and compared it with that of a bulk alloyed sample containing 0.2% Ru. It was found that the two alloys performed similarly and that both had improved corrosion resistance compared to the base alloy without any Ru addition to it.

The main features of the influence of noble-metal additions on the corrosion resistance of the various alloy systems are summarized in Table 5.

### 3.22.12 Summary of the Effect of PGMs and other Noble Metals on the Corrosion Resistance of Cr-Based Alloys

From the above discussion, it can be concluded that cathodic alloying additives (PGMs) greatly increase the corrosion resistance of Cr in nonoxidizing acid environments. The processes of active dissolution

and passivation of cathodically modified Cr can be satisfactorily interpreted from a comparison of the different electrochemical processes; the anodic process on Cr, and the process on the cathodic component. It is also evident that the corrosion resistance of Fe–Cr stainless steels can be significantly increased in nonoxidizing media over a large range of concentrations and temperatures by small additions (0.5% or less) of PGMs. The amount of PGMs needed to produce passivity in Fe–Cr alloys can be decreased by an increase in the Cr content. When molybdenum is also present in the base alloy, a further beneficial synergistic effect between molybdenum and the PGMs can decrease the concentration of the PGMs needed for stable passivity even further. The pitting corrosion resistance of Fe–Cr–Mo steels can be impaired by some of the PGMs. The use of various methods for surface alloying has also proved

successful in reducing high corrosion rates, and similar results to those achieved by use of bulk alloying can be achieved in increasing the resistance to corrosion. However, long-term assessment has to be carried out on surface alloying before any conclusive judgment can be reached.

Similarly, the alloying of multicomponent stainless steels with Pd can also lead to a significant increase in the corrosion resistance of such steels especially in more aggressive environments. However, the corrosion resistance of these steels also depends, to a large extent, on the presence and combination of other components, for example, molybdenum, manganese, and nitrogen.

The work carried out by Tomashov *et al.*<sup>59,60</sup> provides some insight into the corrosion behavior of cathodically modified duplex stainless steels. The effect of the addition of Ru on the corrosion mechanism and the corrosion of each phase in duplex stainless steels were further investigated by Potgieter,<sup>66</sup> who found that the increase in corrosion resistance was the most pronounced in the alloy group with the lowest Cr and Ni content. Furthermore, it was shown that the Ru additions lowered the cathodic Tafel slopes, the critical current densities required for passivation and only the ferritic phases underwent preferential dissolution under conditions of active corrosion.

Evidence indicates that, for all cathodically modified alloys of titanium, stainless steel, and Cr, there is an enrichment of the PGMs on the surface of the alloy at the onset of passivation. It seems that, in all cases, the enrichment of the surface of the alloy during the corrosion process can be explained as being due to a diffusion mechanism.

### 3.22.13 The Nature of the Passive Film on Cathodically Modified Alloys

There are various ways in which the corrosion resistance of an alloy can be improved. The formation of stable oxide layers constitutes one such method. Stainless steels owe their corrosion resistance largely to the formation of passivating oxide layers on the surface of the alloys. However, the effect of PGMs and/or their incorporation in stainless steels on the composition of the passive surface layer has not yet received much attention.

Initially, there is an atmospheric oxide film present on the surface of the cathodically modified alloy.<sup>75</sup> Auger analyses have indicated that the composition and structure of the passive film on some cathodically

modified alloys are similar to those on other stainless steels.<sup>76</sup> It is accepted that the less noble components of stainless steel, for example Cr and iron, oxidize the fastest during the initial stage of active dissolution, thus leaving the noble metal atoms originally present in solid solution as adatoms on the surface of the alloy. Since the noble metal atoms do not oxidize at the low potentials normally encountered during active dissolution, they accumulate on the surface of the alloy. Once a sufficient quantity has accumulated, it can cause spontaneous passivation of the alloy to occur. Although there is ample evidence from various sources<sup>11,23,32,55,75–77</sup> that there is an accumulation of the cathodic component, present in solid solution in the alloy, on the surface of the alloy during the first few minutes of active dissolution, before the passive state is established, very little is known about the nature of the passive film itself, and only a few investigations have been carried out.

### 3.22.14 Russian Studies

Tomashov *et al.*<sup>60</sup> concluded that, in the absence of preliminary etching, Pd which is originally present in solid solution in the alloy, is incorporated into the passive film formed on a Fe–25% Cr–6% Ni–3% Mo–N–0.2% Pd alloy after exposure in HCl, but that in the case of preliminary etching in the active region, Pd accumulates on the surface of the alloy in the form of an independent phase. Furthermore, it seems that Pd increases the stability of the passive film. It was also found that the simultaneous presence of Pd and molybdenum in an Fe–25% Cr–2% Mo–0.3% Pd alloy in nonoxidizing acids promotes more stable passivity than do either Pd or molybdenum alone.<sup>48</sup> This is attributed to the direct influence of molybdenum on the anodic process, as well as the assumption that molybdenum was incorporated in the passivating film on the steel.

Tomashov *et al.*<sup>77</sup> also determined that an Fe–25% Cr alloy to which Ru is added, passivated easier in 5–50% H<sub>2</sub>SO<sub>4</sub> and 1–5% HCl at 50–100 °C than did a similar alloy with an equal Pd content.

Electron microscopy indicated that the surface layer on the Fe–25% Cr–2% Pd alloy consisted mainly of a chromic oxide (Cr<sub>2</sub>O<sub>3</sub>) film with metallic Pd precipitates, while no metallic Ru particles were detected in the chromic oxide film on the surface of the Fe–25% Cr–2% Ru alloy. On this basis it was concluded that one of the reasons for the better resistance of the Ru-containing alloy as

compared to the Pd-containing one, was due to the fact that a large fraction of the accumulated Ru was not present in the form of an independent phase, but was included in the composition of hydroxide and oxide layers that had formed on the surface of the alloy, thereby increasing the resistance of these layers.

A detailed electron microscopy study, by Tomashov *et al.*<sup>23</sup> of the accumulation of Pd on the surface of an Fe–25% Cr steel during active corrosion in H<sub>2</sub>SO<sub>4</sub> revealed that the particle size of the accumulated Pd depends on the temperature at which dissolution took place, as well as on the Pd concentration in the steel. This was confirmed by Higginson *et al.*,<sup>76</sup> who also found that the concentrations of Ru were higher on the passive surfaces of Fe–40% Cr–0.1% Ru alloys than on the passive surfaces of Fe–40% Cr–0.2% Ru. He furthermore established that the accumulation of Ru on the surfaces of Fe–40% Cr–(0.1–0.2%) Ru also depended on the kind of acid in which corrosion took place.

The composition and morphology of the passive surfaces of the cathodically modified alloys studied by Higginson *et al.*<sup>76</sup> are those predicted by Pickering<sup>22</sup> in his review of selective dissolution for alloys containing low concentrations of the noble metal. These results in addition confirm that the chloride ion tends to produce a coarser distribution, thus supporting the suggestion that the chloride ion increases the rate of surface diffusion of Ru during selective dissolution.

### 3.22.15 The Fe–40% Cr–PGM System

Although Higginson *et al.*<sup>76</sup> detected Ru with Auger analysis in the Fe–40% Cr–(0.1–0.2%) Ru alloy after spontaneous passivation in 0.5 M HCl and in the Fe–40% Cr–0.1% Ru alloy after spontaneous passivation in 0.5 M H<sub>2</sub>SO<sub>4</sub>, they only concluded that the enrichment in Ru occurred at the metal oxide film interface, without elaborating on the possible inclusion of the Ru in the passive film. Finer detail about the precise nature of the passive film on Fe–40% Cr–Ru alloys was obtained in a study by Tjong.<sup>61</sup> Tjong confirmed observations by Higginson *et al.*<sup>76</sup> that more Ru is present on the surface of the Fe–40% Cr–0.1% Ru alloy after spontaneous passivation in 0.5 M HCl than in the case of the alloy containing 0.2% Ru and ascribes this to the fact that active dissolution preceding passivation of the 0.1% Ru alloy in 0.5 M HCl is

faster than that of the Fe–40% Cr–0.2% Ru alloy. As a result, larger amounts of Ru adatoms are accumulated on the surface of the alloy containing 0.1% Ru than on that of the alloy containing 0.2% Ru. In both alloys passivating spontaneously in 0.5 M HCl, considerable enrichment of Cr as well as Ru occurs in the passive films. Tjong<sup>61</sup> estimated that the thickness of the passive film on the Fe–40% Cr–0.2% Ru alloy, after spontaneous passivation in 0.5 M HCl, was ~3.2 nm.

Tjong<sup>61</sup> also agrees with Higginson *et al.*<sup>76</sup> that Ru is only incorporated in the passive film of the Fe–40% Cr–0.1% Ru alloy after spontaneous passivation in 0.5 M H<sub>2</sub>SO<sub>4</sub> and could not be detected for the Fe–40% Cr–0.2% Ru under similar conditions. However, when X-ray photoelectron spectroscopy (XPS) was used, the presence of Ru in the passive film on Fe–40% Cr–0.2% Ru after passivation in 0.5 M H<sub>2</sub>SO<sub>4</sub> was detected in the form of Ru<sup>4+</sup>. Tjong<sup>61</sup> concluded that it is likely that both Ru hydroxide as well as RuO<sub>2</sub> may be present in the passive film. It was pointed out earlier by Tomashov *et al.*<sup>77</sup> that in Cr steel containing Ru, that the Ru tends to be incorporated into the hydroxide or oxide layers formed on the Cr steel. The presence of Ru<sup>4+</sup> was also detected in the passive films formed on Fe–40% Cr–0.1% Ru after exposure to 0.5 M H<sub>2</sub>SO<sub>4</sub> and both Fe–40% Cr–0.1% Ru and 0.2Ru after spontaneous passivation in 0.5 M HCl. Tjong<sup>61</sup> thus proved that Cr and Ru are both incorporated in the passive films formed spontaneously on the Fe–40% Cr–0.1% Ru and Fe–40% Cr–0.2% Ru alloys in both hydrochloric and sulfuric acid solutions as Ru<sup>4+</sup> and Cr<sup>3+</sup> species. Further evidence for the incorporation of Ru into the passive film as Ru<sup>2+</sup> species, comes from the work of Kato and Sakaki<sup>31</sup> who investigated the passivation of Cr–Ru materials in sulfuric acid with AES and XPS.

In another study of the Fe–40% Cr alloy system, Tjong<sup>78</sup> found a remarkable difference in the nature of the passive films formed on an Fe–40% Cr–0.2% Pd alloy that passivated spontaneously and under potentiostatic control in 0.5 M HCl at 25 °C. A comparison of the AES composition depth profiles as well as in the [Cr]/[Cr] + [Fe] concentration ratios with sputtering time reveals that there is a marked difference in the composition of the passive films formed under different conditions. The passive film on the Fe–40% Cr–0.2% Pd alloy that underwent spontaneous passivation in 0.5 M HCl was estimated to be 2.4 nm thick and was enriched in Pd relative to Cr. The enrichment of Pd was responsible for the occurrence of spontaneous passivation. In the passive film formed on this same

alloy under potentiostatic control at 220 mV for 40 min, strong enrichment in Cr was found. No Pd was incorporated into this passive film. XPS measurements on both passive surfaces indicated that the Pd is present in the spontaneously passivated film as  $\text{Pd}^{2+}$ , whereas Cr is present as  $\text{Cr}^{3+}$ . This is a significant finding which indicates that there is a difference in the type of oxide formed by different PGMs when spontaneous passivation of Fe-40% Cr-0.2% PGM alloys occur in 0.5 M HCl.

In another investigation<sup>79</sup> of the passivation of Fe-40% Cr-(0.1–0.2)% Pt alloy in 0.5 M HCl at 25 °C, Tjong<sup>79</sup> found that the passive film that formed on these alloys is extremely thin, that is,  $\sim 1.6$  nm. Although Auger spectra did not detect the presence of Pt in the passive surfaces of the Fe-40Cr-Pt system, XPS measurements revealed the existence of the Pt-passivating species and the fact that the surface film contains two Pt species, that is,  $\text{Pt}^{2+}$  and  $\text{Pt}^0$  (metallic Pt).

### 3.22.16 Other Quaternary and Ternary Fe-Cr Alloys with PGMs

Tjong<sup>80</sup> also investigated the passivation characteristics of an FeCrNiMoRu ferritic stainless steel containing 22% Cr, 5% Ni, 3% Mo, and 0–0.3% Ru in 0.5 M HCl at 25 °C. XPS analysis of the passive film on the FeCrNiMo alloy containing 0.3% Ru after spontaneous passivation in 0.5 M HCl showed the presence of three molybdenum species, namely  $\text{Mo}^0$ ,  $\text{Mo}^{4+}$ , and  $\text{Mo}^{6+}$ , in the passive film. The presence of molybdenum in the spontaneously formed passive film indicated that the film is thin enough to allow escape of photoelectrons ejected from the substrate alloy through the film. It was also found that nickel and Ru were absent and did not accumulate in the passive film.

Auger and XPS analyses on passivated films on Fe-24% Cr containing sputter-deposited Pd and exposed to 0.5-M HCl, revealed that a thick Cr oxide layer formed on the Pd enriched surface of the alloy.<sup>44</sup> XPS analysis of a similar base alloy containing ion implanted Ru after exposure to 0.5 M  $\text{H}_2\text{SO}_4$  showed that Ru is incorporated as  $\text{Ru}^{4+}$  in the passive film formed on the alloy.

Studies by Potgieter *et al.*<sup>81</sup> and Baradlai *et al.*<sup>82</sup> on Fe-22% Cr-9% Ni-3% Mo-(0–0.3%) Ru alloys spontaneously passivated in 1–20% sulfuric and 1–2% hydrochloric acid with *in situ* radiotracer methods, AES and XPS analyses, indicate a strong bisulphate/sulphate

accumulation on the alloys' surfaces that is related to the redistribution of the main alloying elements (Cr, Ni, Mo), as well as Ru, in the surface oxide films formed on the steels. The steel containing 0.3% Ru which passivated spontaneously in the HCl showed a significant enrichment of Mo. Cr seems to be mostly present as  $\text{Cr}_2\text{O}_3$  (deeper region) or  $\text{Cr}(\text{OH})_3$  (outermost range). Various types of iron oxides ( $\text{Fe}_3\text{O}_4$ ,  $\text{Fe}_2\text{O}_3$  and  $\text{FeO}(\text{OH})$ ) were also observed. The  $\text{Fe}_3\text{O}_4$  and  $\text{Cr}_2\text{O}_3$  contents were higher in the samples containing Ru than in those without it. Another investigation by the same group<sup>83</sup> using ordinary type-316 stainless steel and a 316 alloy containing 0.5% Ru, shows that after exposing it to HCl and  $\text{H}_2\text{SO}_4$ , selective dissolution of the less noble components occur first, while the majority of the surface defect sites are occupied by Cr, Ni, Mo, and Ru species. The enhanced protection and stability of the passive layers on the 316 + 0.5% Ru are most likely related to the changes in the chemical state and redistribution of these alloying elements on the surface. Myburg *et al.*<sup>84</sup> compared the surface composition of passive layers of an Fe-22% Cr-9% Ni-3% Mo with and without 0.3% Ru after passivation in 0.1 M HCl and 1 M  $\text{H}_2\text{SO}_4$  with each other after AES and XPS analyses, and concluded that the passive film of the alloy having a Ru addition contained more  $\text{Cr}_2\text{O}_3$  and  $\text{Fe}^{2+}$  than  $\text{Cr}(\text{OH})_3$  and  $\text{Fe}^{3+}$ , than was found for the alloy without Ru. Their observations correlated with the fact that Ru and Ni act as blocking agents and therefore increase the probability to form a stable passive layer.

Olefjord and Elstrom<sup>85</sup> have reported that the beneficial effect of nickel is not connected with the occurrence of this metal in the passive film. Instead the accumulation of nickel in the underlying alloy surface decreases the dissolution rate in the active condition and thereby enhances the formation of the anodic passive film.<sup>86</sup> It has been pointed out previously by Tomashov *et al.*<sup>87</sup> that Ru blocks lattice point defects during active dissolution and thereby decreases the dissolution rate of Cr from the active sites. It is believed that molybdenum exhibits similar blocking characteristics. It is therefore clear that Mo, Ni, and Ru are competing species in promoting self-passivation. The absence of Ru from the XPS spectra can be explained by taking into account the fact that the molybdenum concentration is  $\sim 10$  times higher than that of the Ru. Therefore, the molybdenum adatoms presumably blocked the majority of the active surface sites prior to passivation, while only a small number of defect sites are blocked by Ru adatoms. After spontaneous passivation the molybdenum adatoms were incorporated into the film as  $\text{Mo}^{4+}$  and

Mo<sup>6+</sup> species. The XPS measurements also showed that the outermost zone of the passive film that formed on the spontaneously passivated FeCrNiMo alloy with 0.3% Ru consists of Cr and molybdenum hydroxides.

In another investigation on the corrosion behavior of a Fe–24% Cr–6% V alloy containing various amounts of Ru (0.12–0.35%), Tjong<sup>88</sup> concluded from the Auger spectrum that Ru was absent in the passive film on the alloy that passivated spontaneously in 5% HCl solution at 25 °C. This was in contrast to what was found for a spontaneously passivated Fe–40% Cr–0.2% Ru alloy in 0.5 M HCl, where Ru was detected in the passive film. However, the Auger spectrum does show the presence of both Cr and vanadium in the spontaneously formed passive film. It therefore seems that the presence of Ru in the passive film not only depends on experimental conditions, but also on the alloy composition and the presence of other alloying elements.

According to Tjong,<sup>88</sup> the absence of Ru in the spontaneously formed passive film on the Fe–25% Cr–6% V–0.35% Ru alloy can be explained in terms of the competition between vanadium and Ru in blocking the surface-defect sites of the lattice. Because the concentration of vanadium is about 20 times greater than that of Ru, most of the surface defect sites are blocked by vanadium rather than Ru. It was also found that both Cr and vanadium were enriched in the passive film formed on this alloy. The thickness of the passive film was estimated to be approximately 1.8 nm.

Peled and Itzhak<sup>89</sup> investigated the nature of the passive films on hot pressed and sintered 316 stainless steel containing Cu, Au, Pd, and Pt additions of various concentrations after spontaneous passivation occurred in 0.5 M H<sub>2</sub>SO<sub>4</sub>. Auger spectroscopy indicated a maximum in the molybdenum concentrations at a depth of about 0.6 nm in all the passive steel samples, regardless of the composition. These observations mean that molybdenum is accumulated in the passive film. Furthermore, it was found that the oxide-film thickness of passive samples containing Au, Pd, and Pt was about 12–15 nm as compared to about 2–3 nm for passive sintered 316 stainless steel. This was ascribed to the low cathodic overpotential of Au, Pd, and Pt which enhance hydrogen evolution in the cathodic areas and promote the creation of a passive oxide layer in the anodic areas, thus resulting in a thicker oxide film. However, marked enrichment of copper was found on the surface of the passive, Cu-containing, sintered stainless steel samples after exposure to H<sub>2</sub>SO<sub>4</sub>, while only a slight

surface enrichment of the noble alloying elements was observed in the passive samples containing Au, Pd, and Pt.

### 3.22.17 Summary of the Current Observations about the State of Passive Film Compositions on Cathodically Modified Alloys

The following statements can be made to summarize the current state of knowledge regarding passive films formed in reducing acid media:

- i. Accumulation of PGMS originally present in solid solution in the alloy occurs on the surface of the alloy during the initial dissolution period.
- ii. Alloying elements such as Mo, V, and Ni can compete with the PGMs in blocking active surface sites during the initial stage of the corrosion process. This might result in the PGMs not being detected in the formed passive film, especially if the concentration of the other alloying elements is significantly higher (>10 ×) than that of the PGMs.
- iii. The amount, particle size, and morphology of the accumulated PGM on the surface alloy depend on the temperature at which the dissolution occurs as well as the medium in which it is taking place. Greater amounts of PGMs are found on surfaces of alloys that corroded in HCl than on those that were placed in H<sub>2</sub>SO<sub>4</sub>. This is attributed to increased surface-diffusion rates of the PGM adatoms in the presence of Cl<sup>−</sup> ions. Another factor that influences the accumulation of PGMs on the alloy surface is its initial concentration in the alloy. In alloys with lower PGM concentrations, active dissolution occurs faster and results in more adatoms accumulated on the final passive surface.
- iv. There is a difference in the passive films formed spontaneously and those formed under potentiostatic control. In the former case the PGM is incorporated in the passive film as an oxide, while in the latter case it is not, and is only present in an accumulated metallic form.
- v. Different PGMs form different types of oxides on passivated surfaces. Ru occurs as Ru<sup>4+</sup> in the passive film after spontaneous passivation in H<sub>2</sub>SO<sub>4</sub> and HCl, while Pd is incorporated into the passive film as Pd<sup>2+</sup> after spontaneous passivation of the same base alloy in HCl, or occurs in

the  $\text{Pd}^0$  form on the surface. Pt can occur in both the  $\text{Pt}^{2+}$  and  $\text{Pt}^0$  states in the passive film.

- vi. Determinations of the thicknesses of the passive films formed on cathodically modified stainless steels were carried out on a limited number of ferritic stainless steels that passivated spontaneously in HCl. Vast opportunities exist to extend this kind of investigations to other stainless steels in the same or different media (e.g., in  $\text{H}_2\text{SO}_4$ ) under a variety of conditions. Such an endeavor would shed more light on the role of PGMs and other alloying elements in enhancing the corrosion resistance of cathodically modified alloys.

### 3.22.18 Noble Metal Corrosion Resistance in Reducing Acids

Before closing this chapter, it is necessary to briefly take cognizance of the corrosion resistance of pure PGMs and other noble metals under reducing conditions (typically in hydrochloric and sulfuric acid solutions) to complete the description and understanding of their effects in various alloying systems exposed to such reducing acid conditions. The interest in recent times and the latest information is a result of renewed interest in the use of PGMs and their respective alloy or oxides combinations in various anode configurations for the chlorine–alkali industry for the electrolytic manufacture of chlorine, as well as the use of PGMs in fuel cell applications.

#### 3.22.18.1 Hydrochloric Acid

Kuhn and Wright<sup>90</sup> quoted evidence that the electrochemical behavior of platinum (Pt) in strong hydrochloric acid solutions can be ascribed to a  $\text{PtCl}_6$  corrosion product that changes to  $\text{PtCl}_4$  after passivation. Other sources quoted by Kodera *et al.*<sup>91</sup> confirmed that in the presence of  $\text{Cl}^-$  ions, Pt dissolves as the  $\text{PtCl}_4^{2-}$  or  $\text{PtCl}_6^{2-}$  complex. Apparently the specific adsorption of chloride ions on the electrode surface begins immediately after hydrogen desorption. In the same report it is mentioned that iridium (Ir) resist corrosion more than Pt and that it dissolved as  $\text{IrCl}_6^{3-}$  and  $\text{IrCl}_2^{2-}$  if the HCl concentration in solution is stronger than 3 M. Ru corrodes more readily than Pt and Ir, and Llopis and coworkers<sup>92,93</sup> have found that  $\text{RuO}_4$  was formed on ruthenium (Ru) electrodes which partially dissolved, presumably as  $\text{H}_2\text{RuO}_5$ , during anodic CV sweeps in hydrochloric acid solutions.

Sandenbergh and van der Lingen<sup>94</sup> calculated Pourbaix diagrams for Pd–Cl– $\text{H}_2\text{O}$  and Ru–Cl– $\text{H}_2\text{O}$  systems with 250 g l<sup>-1</sup> HCl using Stabcal software with the NBS and Uncritical databases and found that Ru should only oxidize (corrode) at potentials more positive than 0.347 V (vs. SHE) or 0.106 V (vs. SCE), while for Pd the values should be more positive than 0.180 V (vs. SHE) or -0.061 V (vs. SCE). Their experimental results were in excellent agreement with these theoretical predictions, thus lending credibility to their reported values of  $3.6 \times 10^{-6}$  and  $2.8 \times 10^{-3}$  A cm<sup>-2</sup> for the exchange current densities of Ru and Pd in 25% (m/m) HCl, respectively. These authors cautioned though that the values that were obtained are dependent on prior exposure time and surface enrichment of the alloying elements and should not be interpreted as steady state data.

#### 3.22.18.2 Sulfuric Acid

Pourbaix's diagram predicts that Pt metal will dissolve as  $\text{Pt}^{2+}$  during anodic polarization in strong acid solutions. In sulfuric or nitric acid solution the electrolyte enhances the passivation of Pt, especially in 0.5–5 M solutions, and the extent of corrosion seems to be dependent on the formed platinum oxide,<sup>91</sup> which is presumably  $\text{PtO}$ .<sup>90</sup> In more concentrated sulfuric acid solutions of 14–18 M, sulfur deposition seems to occur on the Pt electrode surface by cathodic polarization, which induces Pt corrosion under anodic polarization. The corrosion mechanism is thus different in dilute and concentrated sulfuric acid solutions, something which has also been observed in terms of nickel's behavior as an alloying element in stainless steels.<sup>95</sup> In an effort to understand and improve the dissolution behavior of Pt in polymer electrolyte fuel cells (PEFCs), Mitsushima *et al.*<sup>96</sup> reported a solubility of Pt of  $3 \times 10^{-6}$  M at 25 °C in 1 M  $\text{H}_2\text{SO}_4$  which increases with higher temperatures and increasing acid concentration. They postulated that platinum solubility in an oxygen-containing atmosphere would occur according to the dissolution reaction:

Ota *et al.*<sup>97</sup> reported a dissolution rate of  $5 \mu\text{g A}^{-1} \text{h}^{-1}$  for Pt in 1 M  $\text{H}_2\text{SO}_4$  at 40 °C and the formation of a monolayer of platinum oxide, probably  $\text{PtO}$ , when Pt is anodized under mild conditions. It was found that the corrosion of Pt is always lower in

sulfuric acid solutions than in hydrochloric acid solutions of similar concentration, because the sulphate anions do not coordinate with the dissolved Pt ions in the way the chloride ions form chlorocomplexes referred to earlier.

In sulfuric acid solution Ru can passivate due to the formation of  $\text{RuO}_4$ .<sup>92</sup> Lezna *et al.*<sup>98</sup> reported electrochemical evidence which indicated that the O-layer formation and reduction of Ru in sulfuric acid depend on the range over which the potential is cycled. The anodic reaction initiated when the potential exceeds the equilibrium potential of 0.455 V for the reaction:

yields the equivalent of a monolayer of probably a mixture of oxygen-containing species such as  $\text{Ru}_2\text{O}$ ,  $\text{Ru}(\text{OH})$ , or  $\text{RuO} \cdot \text{H}_2\text{O}$  during the first stage of the electrooxidation process. This can change to  $\text{Ru}_2\text{O}_3$  and  $\text{RuO}_2$  as the potential is increased to 1.4–1.5 V (vs. SCE). Although no specific formula is given for it, a formal oxide of Ir begins to form at about the potential of oxygen evolution in 0.5 M  $\text{H}_2\text{SO}_4$ , and this oxide is only reduced in the hydrogen adsorption and evolution region.<sup>92,93</sup>

According to Pourbaix<sup>99</sup> the standard potentials for several noble metals dissolving are 0.80 V for  $\text{Rh}/\text{Rh}^{3+}$ , 0.99 V for  $\text{Pd}/\text{Pd}^{2+}$ , 1.19 V for  $\text{Pt}/\text{Pt}^{2+}$  and 1.50 V for  $\text{Au}/\text{Au}^{3+}$  versus RHE. Rand and Woods<sup>100</sup> reported similar values in their investigating on the dissolution of Pt, Pd, Rh, and Au electrodes in 1-M sulfuric acid solutions at 25 °C and emphasized that the amount of metal dissolved during a potential sweep (e.g., as in CV) will depend both on the nature and pretreatment of the electrode, on the experimental conditions, any stirring of the solution and the surface's structure. Their work supported a direct anodic dissolution mechanism of the noble metals according to the general reaction:

and the amounts of dissolved metals analyzed in solution correlated well with their electrochemical measurements and other reported values in the literature. It should be kept in mind that all the postulated oxide species formed on the surfaces of PGMs and noble metals during oxidation/corrosion were based on electrochemical data and little evidence could be found of surface analytical measurements to support the electrochemical data.

### 3.22.19 Final Conclusions

Despite the work during the last 50–60 years in this field, there are still a number of unanswered questions, and matters to be resolved. It is clear that the effects of cathodic modification in enhancing corrosion resistance are definitely more dramatic in ferritic stainless steels than in austenitic or duplex stainless steels. If Pd is replaced by Ru, then the maximum Cr content at which the largest decrease in the corrosion rate in superferritic (Fe–40% Cr) alloys is observed, can be lowered by at least 10%, which can have enormous cost and workability advantages. Because surface alloying seem to be equally efficient to bulk alloying in increasing the corrosion resistance of various stainless steels, it is definitely a more cost effective option to exploit in terms of practical applications of cathodically modified stainless steels for process equipment manufacture. However, it is not clear if cathodically modified stainless steels will always remain too expensive for uses other than those where safety hazards are the overriding concern and everything else is therefore of secondary importance.

### Glossary

**Exfoliation** The process of separation or shedding of layers of a structure, caused by mechanical abrasion, or particularly intercalation within a structure, resulting in the disruption of the bonding forces between 2-dimensional sheets of a material, such as graphite.

**Fullerene** A generic molecular structure for carbon, comprising linked polygonal sheets that build into a 3-dimensional structure such as a tube or ball and which resembles the geodesic dome structures originally designed by the architect Buckminster Fuller, after whom such structures are named.

**Intercalation** An ionic or molecular process that comprises the entry, or exchange, of species into a 2- or 3-dimensional lattice structure, for example, between the 2-D-layered

sheets that constitute graphite. Such entry often results in significant changes in physical or chemical properties of the structure.

### 3.24.1 Technical Carbon and Graphite

#### 3.24.1.1 Introduction

Natural flake graphite was known in ancient times as a mineral with well described properties, albeit in small volumes. However, the material became of technical interest only when an electric resistance furnace, capable of graphitization of carbonaceous materials and production of materials in large dimensions, was developed by Acheson in 1895.<sup>1</sup> Currently, only a few mines supply natural graphite, the main producing countries being China, Ukraine, Brazil, Russia, and Canada, although many mines produce

the less-valuable amorphous material in small volumes and not the more-valuable flake graphite. In the United Kingdom, a small graphite mine near Kendal was the basis of the Lakeland pencil manufacturing industry.

Baked carbon and industrial graphite can be manufactured from almost any form of carbonaceous precursor that leaves a carbon-rich material when heated in the absence of air. The main difference between the two substances is that graphitization requires furnace baking for much longer periods at higher temperatures and is therefore considerably more costly. However, its properties, for example, electrical conductivity, high temperature strength, etc., are greatly superior to baked carbon. In view of the limited natural resources, the main carbon precursors for carbon and graphite manufacture are generally cokes derived either from petroleum or coal, the former giving the highest purity and lowest ash content.

Carbon atoms can coordinate in several different ways with adjacent atoms. Thus, in the  $sp^3$  form, carbon is tetragonally coordinated in 3 dimensions, while in the  $sp^2$  form, carbon is trigonal planar.<sup>2</sup> Although carbon is obviously most abundant in nature in the form of various coals (largely, amorphous carbon containing various amounts of volatile materials and ash), this key difference in bonding is well exhibited in carbon's naturally occurring allotropes: graphite ( $sp^2$  bonding in 2-D macromolecular sheets), and most appealingly, diamond ( $sp^3$  bonding in 3-D macromolecules). In recent years, however, it has also been recognized that carbon can form a multitude of polymeric-like structures and macromolecules based particularly on  $sp^2$  bonding, for example, fullerenes.

### 3.24.1.2 Baked Carbon

At atmospheric pressure, carbon does not melt, but sublimates at very high temperatures (above 4000 °C). It can, therefore, only be manufactured using conventional ceramic processing routes. Thus, the precursor material (e.g., coal-derived coke) is initially ground to a desired particle size range, and then a clay-like green compact is formed with petroleum pitch or coal tar as binder. This is then formed into a final or near-net shape compact typically by extrusion, die-molding, or isostatic pressing. Significant anisotropy may be developed during such compact formation, especially with extruded materials. Also, the considerable shrinkage that will take place during heating has to be taken into account in the initial

dimensions of the green compact. After formation, the green compact is then baked in a pyrolysis furnace (i.e., with the exclusion of air) in order to eliminate oxidation and to ensure the carbonization of the pitch binder and the removal of volatile species by diffusion. During this process, it is important to limit the initial heating rate and temperature in order to ensure dimensional stability of the material. Depending on the application and the precursor, the initial pyrolysis temperatures are typically from 200 to 500 °C, with a final baking temperature of 650–900 °C. To avoid excessive cracking and porosity, large dimensioned samples require slow heating and cooling with furnace cycles of tens of days possible.

Carbon products from a single baking cycle are usually relatively porous (15–25 % porosity). Thus, although there are some uses for porous carbons (e.g., for the infiltration of copper for carbon brushes in electric motors, etc.), such products are, more generally, subjected to repeated cycles of pitch infiltration and baking in order to reduce porosity to desired levels (Figure 1).

### 3.24.1.3 Industrial Graphite

Baked carbon precursors may be graphitized by further heat treatment, using direct resistance heating with water-cooled electrodes. This further improves the mechanical and electrical properties of the material and also reduces the ash and volatile content. However, additional shrinkage takes place during the graphitization process. Initially, the temperature is raised to between 900 and 1200 °C where any residual pitch filler is fully carbonized. Thereafter, the temperature is raised in stages: from 1500 to 2000 °C, residual impurities such as hydrogen and sulfur are volatilized; above 2200 °C, a significant graphite crystallization commences; above 2600 °C, the graphite crystallite growth predominates; finally, at ~3000 °C, the electrical and mechanical properties become optimal. At this point, the residual impurity content (mostly as nonvolatile metal-containing ashes) should be below 1000 ppm, which is sufficient for the majority of purposes. Prolonged treatment at higher temperatures can further reduce this value to 200–300 ppm. The total cycle time of heating and cooling may take several tens of days.

Normally, the levels of residual impurity after high temperature graphitization are adequate for most purposes. However, very high-purity grades such as nuclear graphite require further lower-temperature thermal treatment using halogens, or

**Figure 1** Schematic diagram showing the progressive graphitization of carbon. Reproduced from Marsh, H. *Carbon* 1991, 29, 703–704, with permission from Elsevier Publications.<sup>3</sup>

more commonly, halogen-containing compounds (e.g., carbon tetrachloride) in order to convert residual metal species to volatile halides. In this way, the residual impurity level can be reduced to below 1 ppm.

#### 3.24.1.4 Glassy Carbon

Vitreous or glassy carbon is important because of its low reactivity (high corrosion resistance). These are generally produced by the pyrolytic decomposition of thermoset polymer resins (e.g., phenolic resins), with or without fiber reinforcement (e.g., by cellulose or rayon).<sup>4</sup> Carbonization occurs in the solid phase, and there is no significant crystallite growth or porosity development even at graphitizing temperatures. The production of this type of carbon requires moderate and carefully controlled baking rates, because large volumetric contractions occur (~50%) and considerable volumes of volatiles are emitted.

#### 3.24.1.5 Pyrolytic Graphite

Carbon may be directly deposited on a heated substrate by the decomposition of hydrocarbons such as methane, benzene, or acetylene. The reaction conditions determine how the deposition occurs (i.e., surface or gas phase polymerization), but it is essential

to avoid soot formation in the gas. The structure of pyrolytic graphite can be varied from randomly oriented (i.e., essentially isotropic and nanocrystalline) to highly oriented material of near theoretical density. The high anisotropy of this latter material leads to markedly different properties in directions parallel and perpendicular to the graphite planes. This feature is an advantage particularly in heat transfer applications where high conductivity in one or two directions is desired to be combined with poor conductivity in a third direction.

#### 3.24.1.6 Carbon Fiber and Carbon Composites

Carbon fibers essentially comprise long bundles of linked graphite plates in a highly oriented crystal structure layered parallel to the fiber axis. This results in extreme anisotropy, with elastic moduli of up to 200–400 GPa on-axis versus only 35 GPa off-axis. Carbon fibers can be manufactured from several different precursor fibers, such as polyacrylonitrile, rayon, etc., and by high temperature pyrolysis with or without pretensioning, usually in a two-stage process with initial carbonization at ~1500 °C followed by graphitization at ~3000 °C. In such ways, the properties of the resulting fibers can be varied somewhat to emphasize

either high strength (2000–5000 MPa) or high stiffness (200–400 GPa). Given the range of densities for carbon fibers ( $1.7\text{--}1.85\text{ g cm}^{-3}$ ), they have outstanding specific strength and stiffness characteristics.

Carbon fibers may be used with a variety of matrix phases, including polymer composites (e.g., epoxy–carbon) and carbon–carbon composites (fiber-reinforced graphite). The latter can be made via vapor deposition routes; however, these are generally slow and costly. Alternatively, methods involving fibers can be impregnated into a thermoset resin (e.g., phenolic) or petroleum pitch, followed by further pyrolysis steps.

### 3.24.1.7 Other Forms of Carbon: Fullerenes and Carbon Nanostructures

Until 1985, carbon was thought to exist only in two allotropes: diamond and graphite. This changed when, using mass spectroscopy, an entirely new form of carbon was found in which the atoms are arranged in closed structures. The original discovery, for which the Nobel Prize for Chemistry was awarded in 1996, was for the isolation and the identification of the  $C_{60}$  molecule, which is shaped like a soccer ball (i.e., consisting of alternating pentagons and hexagons). Such closed-shaped molecules are named fullerenes because of their resemblance to the geodesic domes first constructed by the architect R. Buckminster Fuller. Since 1985, many additional fullerene molecules have been identified, and furthermore, several additional molecular shapes, often based on rolled up sheets of graphite, have been identified, for example, carbon nanotubes. Many of these materials have interesting electrical and other characteristics, and there is hope that they will eventually outgrow the laboratory and become industrially useful.

### 3.24.1.8 Final Manufacture and Surface Finishing

Baked carbon and industrial graphite are both fully machinable with the use of conventional tools, although carbide or diamond-tipped tools are preferable especially when cutting lower-porosity glassy carbon because of its higher hardness. Additional treatments that seal the surface and/or internal porosity are also often used. These include, for example, sealing/impregnation with organic materials such as phenolic resins or Polytetrafluoroethene

(PTFE) (although this will limit the application temperature to below  $\sim 200^\circ\text{C}$ ) and a final impregnation with pitch followed by a low-temperature pyrolysis process. High temperature degradation (usually by oxidation) may be reduced by impregnation with inorganic salts, such as borates and phosphates, which melt at operating temperatures, sealing the pores. All forms of carbon may be coated with, for example, silicon carbide, silicon nitride, or high-density pyrolytic graphite by chemical vapor deposition. Such treatments can provide greatly improved oxidation and chemical (wet corrosion) resistance.

## 3.24.2 General Characteristics

Carbon and graphite have a number of useful and even unique properties that may be summarized as follows:

- retention of modulus, strength, and erosion resistance to very high temperatures (up to  $3200^\circ\text{C}$  in nonoxidizing atmospheres);
- low coefficient of thermal expansion and high thermal conductivity (25% of copper), giving rise to excellent thermal shock resistance;
- high corrosion resistance and a wide resistance to chemical attack except to strongly oxidizing species;
- significant electrical conductivity especially in fully graphitized materials;
- low friction and self-lubrication in graphitized grades;
- controllable porosity, giving a spectrum of structures from dense, hard materials to nanoporous materials with very high surface area;
- efficient moderation of fast neutrons and scattering of thermal (i.e., slow) neutrons, coupled with a low-absorption cross section for both thermal and fast neutrons in high-purity grades

The physical properties of a number of grades of carbon are summarized in [Table 1](#). It should be noted, however, that the material properties will vary over a wide range depending upon the original source of carbon (e.g., natural graphite, petroleum coke, or coked coal), the original powder size prior to sintering, the binder used (e.g., petroleum pitch, coal tar, etc.), and the temperature and time of heat treatment, including the number of cycles of pitch infiltration and recarbonization. Also, depending on the initial morphology of the input carbon source

**Table 1** Typical properties of carbon and graphite materials<sup>5</sup>

Property	Baked carbon	Industrial graphite	Glassy carbon	Pyrolytic graphite
Bulk density ( $\text{mg m}^{-3}$ )	1.65–1.8	1.7–1.9	1.3–1.5	2.1–2.2
Nominal porosity (%)	15–20%	9–18%	25–30%	<1%
Compressive strength (MPa)				–
Modulus of elasticity (GPa)	8–14	10–15	12–20	28–31
Tensile strength (MPa)	0.007–0.016			8–12 //c 110 //ab
Coefficient of thermal expansion ( $\text{K}^{-1}$ )	$3.5\text{--}5.5 \times 10^{-6}$			15–25 //c –1–1 //ab
Thermal conductivity ( $\text{W m}^{-1} \text{K}^{-1}$ )	30–100	100–200	4–10	1–3 //c 190–390 //ab
Electrical conductivity ( $\Omega^{-1} \text{m}^{-1}$ )	200–1000			300–1000 //c 20 000–25 000 //ab
Ash content	<0.2%	<0.1%	1–2%	<1 ppm

(e.g., natural flake graphite), materials produced by extrusion and related processes may retain significant anisotropy in the final manufactured product. Thus, one purpose in using the increasing grinding of the input carbon source is to produce small particle sizes that reduce or eliminate this anisotropy.

Carbon and graphite are unusual in that (in the absence of oxidative degradation) their strength and Young's modulus generally increase with temperature. Thus, the tensile strength of industrial graphite is about twice the room temperature value at 2500 °C, while its modulus is ~40% higher. Fully dense (pyrolytic) graphite generally has outstanding high temperature properties, especially if isotropic (i.e., essentially containing randomly oriented nanocrystallites). More normally, however, its properties are highly directional and vary within the graphite basal plane (*ab*-direction) and across the planes (*c*-direction). This variation is due to the large difference in interatomic distance between in-plane atoms and out-of-plane atoms. This directionality of properties can be utilized for advantage in certain applications, for example, where good heat transfer in one direction is required to be coupled with poor heat transfer in another direction (Figure 2).

The oxidation of carbon and graphite materials leads to the formation of gaseous products (i.e., CO and/or CO<sub>2</sub>) and results in a rapid decrease in properties, especially strength. These reactions begin to become significant above ~350 °C, but can be controlled by reducing or eliminating the porosity of the materials, in which case slow reaction will occur only on the surface of the material, leading to a steady loss of thickness. In the absence of oxidation, the dimensional stability of carbon and graphite materials is

**Figure 2** Schematic diagram showing the atomic structure of graphite. Reproduced from European Carbon and Graphite Association, Avenue de Broqueville 12, B-1150 Bruxelles, with permission from Elsevier Publications.

excellent, provided their final heat treatment temperature is not exceeded. If this occurs, then additional graphitization may take place, leading to shrinkage.

### 3.24.3 Applications

Carbon is relatively inert chemically and thus may be used in all its forms under a variety of corrosive conditions. Many applications depend upon the acceptable electrical and excellent heat conductivity

of carbon and graphite and upon the unique retention of significant strength at very high temperatures. Thus, current major uses include

- carbon anodes in the Hall–Heroult aluminum cell and in electric arc furnaces such as for steel production and remelting; this is by far the greatest tonnage usage;
- heat exchangers, gaskets, seals, etc. for use in the chemical industry;
- furnace linings (e.g., in the iron blast furnace) as well as other high temperature furnace components, including crucibles;
- resistive and inductive susceptor elements in furnace and related specialist activities (e.g., graphite tube furnaces for atomic absorption spectroscopy);
- dies for optical glass fiber drawing and related operations;
- reaction vessels, crucibles, and supports in the electronics industry for Si wafer and especially for III–V semiconductor manufacture;
- heat transfer in brake blocks and other friction components, as well as low friction bearing materials, seals, etc. in the automotive and aerospace industries;
- conductive brushes for slip rings and commutator components in electric motors, etc;
- neutron moderator and reflector materials in the nuclear industry;
- heat-resisting components in aerospace and rocketry;
- biomedical applications (carbon is fully biocompatible);
- Electrodes for conventional batteries and ultrahigh surface area electrodes for lithium ion cells and supercapacitors.
- electrodes in electrolysis cells (e.g., chloralkali production) and cathodic protection anodes, etc.

### 3.24.4 Degradation of Carbon and Graphite

#### 3.24.4.1 Aqueous Corrosion

In aqueous conditions and at room temperature, carbon is thermodynamically unstable to direct oxidation to carbon dioxide, the bicarbonate ion, or the carbonate ion, depending upon the pH, and to direct reduction to methane at all pH. In practice, these reactions are severely kinetically hindered, and apart from oxidation at pH below  $\sim 1$ , occur at negligible rates at all pH up to 100 °C. The only significant

aqueous oxidation processes occur in strongly oxidizing environments such as concentrated nitric acid, perchloric acid, chromic acid, and chromates, or at highly oxidizing (positive) potentials. Thus, at pH 0 and under appropriate conditions, carbon will slowly form carbon dioxide at potentials more positive than  $\sim 0.45$  V on the hydrogen electrode scale (SHE). This implies that carbon/graphite is a relatively noble element – indeed, it is slightly more noble than copper. Therefore, while coupling graphite components to other metals, this important factor should be taken into account.

Most degradation of industrial graphite under aqueous conditions occurs not as a result of oxidation, but as a consequence of the reaction within pores of the material, for example, with residual impurities or binder phases, causing initially localized mechanical damage, but ultimately macroscopic mechanical failure of the component. Alternatively, where chemical species (e.g., chloride ion) can intercalate between the graphite layers, thus causing exfoliation, degradation is greatly increased.

#### 3.24.4.2 Aqueous Environments

The performance of glassy carbon electrodes in sulfuric acid under anodic polarization has been examined at room temperature as a function of acid concentration and anodic current density.<sup>6</sup> It was found that the dominant process of mass removal was via a mechanical mechanism with initial selective oxidative attack in regions of apparent lower density. This appeared to result in a mechanical stress, thus giving rise to local spallation. The formation of  $\text{CO}_2$  as the oxidative product was also confirmed. Degradation did not occur below the potential for oxygen evolution, but above this value was approximately linear with applied anodic current density and with acid concentration up to 4 M  $\text{H}_2\text{SO}_4$ . A degraded surface film,  $\sim 2\text{--}4$   $\mu\text{m}$  in thickness, formed after passage of  $\sim 80\,000$   $\text{C m}^{-2}$ .

The corrosion of industrial graphite was examined in 30% (5.5 M) phosphoric acid at 25 and 80 °C.<sup>7</sup> Under free corrosion conditions in air, the electrochemical potential fell in the range 0.59–0.62 V (SHE), which is somewhat greater than the theoretical value of 0.45 V. Potentiodynamic polarization implied the presence of a surface film, most likely of adsorbed oxygen and hydroxide species. Secondary ion mass spectrometry confirmed this hypothesis and also demonstrated significant penetration of phosphorus within the graphite, either as an

intercalated species, or more likely, adsorbed onto internal porosity (Figure 3).

The mass-loss rates for carbon electrolysis anodes used in brines for chlorine production were examined as a function of temperature, current density, and NaCl concentration.<sup>8</sup> The mass-loss rate was found to decrease with increase in chloride concentration and increase with temperature. The maximum degradation rate was at approximately neutral pH, the rate falling off by a factor of 2–3 under acid (pH 1) and alkaline (pH 11) conditions; at neutral pH, the degradation rate was found to be a function of current density. The degradation mechanism occurred via the reaction of an adsorbed chloride–graphite intermediate. Significant reductions in degradation rate were achieved as the overall porosity of the anodes decreased, and particularly, when the average pore size decreased below  $\sim 5\ \mu\text{m}$ .

The oxidation of high-purity (nuclear) graphite was studied in nitric acid at temperatures between 275 and 300 °C and at 100–120 bar pressure.<sup>9</sup> Under these extreme conditions, graphite is smoothly oxidized to carbon dioxide, while the nitric acid is reduced to nitrogen. Average reaction rates from 0.4 to 1 mol h<sup>-1</sup> were obtained under these conditions.

The corrosion of small graphite tube furnaces, used in atomic adsorption spectroscopy, was studied primarily in order to ascertain the effect of their degradation on the accuracy of analysis.<sup>10</sup> However,

it was found that the order of acid reactivity followed the trend:  $\text{HNO}_3 < \text{HF} < \text{HCl} < \text{HClO}_4$ . This was explained by two tendencies: first, the ability of the aggressive species to intercalate between the graphite sheets, and second, the ability of the species to oxidize the graphite. Thus, hydrochloric acid, which is nonoxidizing but which can intercalate easily because of the small size of the chloride ion, is more aggressive than nitric acid, resulting in mechanical damage (exfoliation) to the graphite.

The electrochemical degradation of glass-like carbon (GC), diamond-like carbon (DLC), and highly ordered pyrolytic graphite (HOPG) were studied in nitric–hydrofluoric acid mixtures at 50 °C.<sup>11</sup> Under repeated potential cycling within the range for water stability, small pits became apparent on the GC electrode and the HOPG electrode became severely roughened. However, a few, if any, morphological changes were evident on the DLC electrode. The heavy degradation of the HOPG electrode was ascribed to the oxidation of intercalated species and the consequent exfoliation of the graphite sheets.

The stability of graphite-reinforced epoxy-composite materials was studied under both galvanic coupling (i.e., where the graphite was a net cathode) and anodic polarization in order to understand electrochemically induced degradation processes. When the composite was connected to sacrificial anode materials in seawater, it suffered a significant (30%) reduction in strength over 140 days' exposure.<sup>12</sup> This was found to be due to the degradation of the graphite–epoxy bond probably via a similar mechanism to cathodic disbondment of organic coatings. Under anodic polarization, significant damage was apparent even at comparatively low current densities of 1  $\mu\text{A cm}^{-2}$ . This was ascribed to direct oxidation of the graphite fibers at local potentials above the oxygen evolution reaction.<sup>13</sup> Consequently, care has to be taken when using carbon fiber reinforcement composite materials where they may become electrochemically polarized.

In summary, all forms of technically important carbon may be degraded in aqueous conditions by two main mechanisms: electrochemical oxidation under anodic polarization (or chemical oxidation using a strong oxidizing agent) and the intercalation of small species between the graphite sheets with consequent swelling leading to the exfoliation of the sheets. Both of these processes may be greatly reduced in extent by use of dense materials of low overall porosity and/or with pore sizes in the micron range.

**Figure 3** Potentiodynamic polarization of graphite in phosphoric acid. Reproduced from Guenbour, A.; Kebkab, N.; Bellaouchou, A.; Iken, H.; Boulif, R.; BenBachir, A. *Appl. Surf. Sci.* **2006**, 252, 8710–8715, with permission from the European Carbon and Graphite Association (page 4 on presentation: “The element C”).

### 3.24.4.3 Galvanic Corrosion

Since carbon/graphite is relatively noble, care has to be taken to ensure its galvanic compatibility with metals in which it is in contact. Thus, graphite is cathodic to most common metals such as steels, and particularly, the light metals aluminum and magnesium. Indeed, early aluminum airframes, which were commonly marked out for cutting using graphite pencils, suffered from corrosion along the residual pencil marks.<sup>14</sup> Also, a cathodic residue of carbon, deposited from lubrication oils during tube drawing, is responsible for the pitting of copper tubing in some natural drinking supply waters. Thus, the general assumption should be that electrical contact between carbon/graphite and other metals under aqueous corrosion conditions should generally be avoided.

As an example, the galvanic corrosion behavior of graphite fiber-reinforced epoxy composites coupled to a series of materials (aluminum alloys AA2024, 7075, and 5052, stainless steels AISI301, 302, 321, 15-5PH, and 17-7PH, carbon steel AISI4340, nickel–aluminum–bronze, and titanium Ti–6Al–4V) was studied.<sup>15</sup> The graphite composite was found to be cathodic in 3.5% NaCl to all of the alloys studied. Relatively high galvanic currents were evident when coupled to all aluminum alloys and to the carbon steel: the corrosion in these cases was effectively limited by cathodic oxygen reduction at the graphite cathode. Dealloying was evident for the nickel–aluminum–bronze material, and hence, coupling this material to graphite is also not recommended. Of the passive alloys, minor pitting was observed for the lower grades of stainless steel, while only titanium was deemed to be wholly safe.

Although graphitic materials are not generally recommended where oxygen reduction is the dominant cathodic process, they are relatively widely used as gasket materials in a crevice situation: where oxygen depletion would be expected. Under these conditions, the electrochemical potential of the graphite will become significantly depressed tending to that of the hydrogen evolution reaction. The likelihood of crevice attack with graphite gaskets was explored by experiment and modeling<sup>16</sup> where it was predicted that, in nonchlorinated seawater, graphite is likely to become anodic to duplex stainless steels, and hence protective, in a tight crevice because of oxygen depletion. However, for lower grades such as AISI316, where initiation is due to micropitting, such protection would not be effective.

### 3.24.4.4 High Temperature Oxidation

Carbon is largely nonreactive in air or oxygen at temperatures below  $\sim 350^\circ\text{C}$ . However, above  $400^\circ\text{C}$  the rate of reaction increases significantly. The principle oxidants are air (i.e.,  $\text{O}_2$ ), steam ( $\text{H}_2\text{O}$ ), and carbon dioxide ( $\text{CO}_2$ ), the main reaction equilibria being:

The  $\text{CO}_2$  shift reaction [2] and the water gas reaction [3] are both thermodynamically unfavorable below  $\sim 700^\circ\text{C}$ , but start to become kinetically significant above  $\sim 750^\circ\text{C}$ . The kinetic reactivity<sup>17</sup> differs greatly as a function of the material's porosity, its residual ash content (i.e., on the presence of oxidative catalysts, such as metallic impurities), and interestingly, also on the form of carbon. Studies of the thermal stability of diamond, graphite, carbon black,  $\text{C}_{60}$  and  $\text{C}_{70}$  fullerenes, and carbon nanotubes were carried out by thermal gravimetric analysis in nitrogen and air.<sup>18</sup> In nitrogen, the low molecular weight materials (i.e., the fullerenes and the carbon black) started to sublime above  $\sim 300\text{--}400^\circ\text{C}$ ; however, graphite and diamond showed mass losses of less than 3% up to  $900^\circ\text{C}$ . In flowing air, the onset temperatures for the reaction of  $\text{C}_{70}$  and  $\text{C}_{60}$  fullerenes were  $\sim 430^\circ\text{C}$  and  $530^\circ\text{C}$ , respectively. Carbon black commenced reaction at  $\sim 505^\circ\text{C}$ , graphite showing significant mass losses above  $\sim 610^\circ\text{C}$ . The carbon nanotube structures were most resistant, with an onset temperature of  $820^\circ\text{C}$ , while diamond had an onset temperature of  $800^\circ\text{C}$ . However, once reaction commenced, oxidation was found to progress rapidly (Figure 4).

Thus, the kinetics of oxidation of different forms of carbon are clearly very different at lower temperatures. However, as the oxidation temperature increases, the surface reactivity becomes less rate-limiting, and above  $800^\circ\text{C}$ , the oxidation rate is determined by mass transfer in the gas phase.<sup>19</sup> For example, the reaction of nuclear graphite with air was found to follow three regimes as a function of temperature.<sup>20</sup> In the lowest temperature range from  $400$  to  $600^\circ\text{C}$ , the reaction exhibited the highest activation energy ( $\sim 160\text{ kJ mol}^{-1}$ ) and was chemical reaction rate controlled. In the intermediate range from  $600$  to  $800^\circ\text{C}$ , the activation energy fell to  $72\text{ kJ mol}^{-1}$ , with the reaction kinetics controlled by

**Figure 4** Thermal gravimetric analysis on carbon materials in flowing air at  $20^{\circ}\text{C min}^{-1}$ . Reproduced from Cataldo, F. *Fullerenes, Nanotubes and Carbon Nanostruct.* **2002**, *10*, 293–311, with permission from Taylor and Francis.

the diffusion of reactant and products within the pores in the material. Above  $800^{\circ}\text{C}$ , the activation energy was low-to-negligible, the rate-controlling step in the oxidation process being boundary diffusion in the bulk gas phase.

#### 3.24.4.5 High Temperature Environments

Carbon will react directly at high temperatures with many nonmetallic elements such as sulfur and halogens and with metallic elements that can dissolve significant quantities of carbon (e.g., iron). The layered structure of graphite is also susceptible to intercalation with a range of species both ionic and molecular (e.g., from molten salts), leading to the disruption and the exfoliation of the graphite layers.<sup>21</sup> This phenomenon is critical in the use of graphite intercalation electrodes in Li-ion rechargeable cells in room temperature molten salts.<sup>22</sup>

Many molten metals will dissolve significant quantities of carbon, iron being the most obvious example of this. Notwithstanding this factor, carbon refractory materials are a critical component of many smelting and purification processes particularly for their outstanding resistance to thermal shock. For example, the hot-air zone of the iron blast furnace (i.e., close to the tuyeres or hot air nozzles) is an extreme environment requiring high temperature stability with resistance to hot gas erosion and large

temperature fluctuations. In view of this, carbon refractories, often impregnated with oxide materials such as zirconia to improve abrasion and erosion resistance, are the materials of choice.<sup>23</sup>

#### 3.24.4.6 Protection against Degradation

For high temperature use, it is normal to protect carbon from oxidation, as relatively small mass losses (e.g., 5–10%) have been found to result in losses of mechanical properties of up to 50%.<sup>19</sup> Alternative gas atmospheres such as  $\text{H}_2$  or  $\text{N}_2$  are most easily used; however, at temperatures above  $\sim 1500$ – $1600^{\circ}\text{C}$ , hydrogen will react to form methane, while nitrogen will react at temperatures above  $\sim 1700^{\circ}\text{C}$  to form cyanogen. Thus, at very high temperatures, inert gas atmospheres, such as argon or helium, are essential. Careful matching of the grade of carbon or graphite to the application, for example by the selection of low porosity (high density) grades, will also help to limit degradation rates both at high temperature and in aqueous conditions.

There has long been a search for coating methods to protect carbon from high temperature degradation, which is predominantly an oxidation problem. Such coatings should match the thermal expansion properties of carbon (to avoid spallation on thermal cycling), should adhere well, should have a low permeability to oxygen, and clearly, should not

themselves degrade/oxidize under the conditions of operation. Coatings that are molten at the operating temperature (i.e., glazes) are obviously resistant to cracking and are self-healing.<sup>24</sup> The most successful of such glazes are based on boron oxide ( $B_2O_3$ ), which melts at  $\sim 500^\circ C$  and starts to volatilize significantly above  $1200^\circ C$ , although their upper limit of operation is  $\sim 900^\circ C$  when their permeability to oxygen starts to become significant.<sup>25</sup> Phosphorus-type glazes may also be used successfully in a similar manner.<sup>26</sup>

Above  $\sim 900^\circ C$ , single layer coatings become increasingly ineffective and multilayer coatings are required. Many types of oxide, carbide, and nitride coatings have been applied with a view to limiting oxidation. The most successful are those based on silicon carbide either in conjunction with boron oxide (i.e., as self-healing agent)<sup>24</sup> or in functional coatings with graded thermal expansion coefficients matched to the substrate.<sup>27</sup> Coatings can be formed using a variety of methods, including sol-gel, pack cementation, and chemical or physical vapor deposition. Silicon carbide is successful, partly because it oxidizes to silicon oxide; however, the upper temperature limit for  $SiO_2$  is  $\sim 1700\text{--}1800^\circ C$  when its vapor pressure starts to become significant; thus, in practice, the practical temperature limit is  $\sim 1650^\circ C$ . Above  $1800\text{--}2000^\circ C$ , nonoxide ceramics become increasingly susceptible to oxidation and many oxide ceramics are not stable to carbothermic reduction. However, for specialist uses, such as rocketry components, which require only a few minutes' or hours' operation at maximum temperature, coatings such as hafnium and zirconium carbides and borides have been implemented successfully.

### 3.24.5 Nuclear Graphite

#### 3.24.5.1 Radiation Damage

The main purpose of graphite in a fission reactor is to slow ('thermalize') fast neutrons, which are emitted during fission, so that they can be recaptured by heavy nuclei in order to maintain the fission chain reaction. Graphite can also act to reflect slow neutrons back into the reactor core, thus improving neutron usage and may find use in a similar role in future fusion reactor systems. To accomplish this goal satisfactorily, nuclear graphite has exceptionally low impurity levels, that is, below a few parts per million. This is because elemental impurities will unacceptably increase the neutron capture cross-section of the graphite. Apart from this difference in

purity, the microstructures of nuclear grades of graphite are essentially similar to other graphite grades except that they generally have lower porosity resulting in improved mechanical properties.

Fast neutrons typically emerge from a fission event with a mean energy of  $\sim 2\text{ MeV}$  (a velocity of  $15\,000\text{ km s}^{-1}$ ). This needs to be reduced to  $\sim 1\text{ km s}^{-1}$  ( $\sim 50\text{--}100\text{ eV}$ ), which is approximately in equilibrium with the surrounding temperature, and hence, these neutrons are known as 'thermal'.<sup>28</sup> Radiation damage in graphite thus occurs as a result of inelastic scattering between the neutrons and carbon atoms that result in the displacement of the carbon from their preferred lattice positions. An incoming neutron will typically require between 500 and 1000 of such scattering events, and travel  $\sim 500\text{ nm}$  (i.e., significant in terms of the lattice spacing), before it is in thermal equilibrium; this results in a significant displacement of the carbon atoms, and consequently, a significant storage of energy (Wigner energy) in the form of an unstable lattice. For room temperature irradiation of graphite, this energy can reach over  $20\text{ MJ kg}^{-1}$ . This is easily more than sufficient, when released in an uncontrolled manner, to raise the temperature of the material spontaneously by several hundred degrees. Graphite-moderated power reactors, however, generally operate at temperatures that are sufficiently high to result in a continuous thermal annealing of the graphite such that the storage of Wigner energy is insignificant.

Neutron irradiation of graphite also results in significant dimensional changes as a consequence of the difference between inelastic scattering within (*ab*-direction) and between (*c*-direction) the graphite layers.<sup>28</sup> Thus, in single crystal graphite, there is a significant expansion in the between-plane direction and a slight contraction in the in-plane direction. In macroscopic graphite, this results in an initial shrinkage of components, but an ultimate expansion of component sizes giving rise to a significant stress generation.<sup>29</sup> Both these factors have to be taken into account in reactor designs. The physical properties of graphite also change as a result of irradiation.<sup>30</sup> In particular, irradiation induces creep within the graphite and also reduces the elastic modulus of the material in the *c*-direction by  $\sim 6\%$ . Also produced are many radiation-induced dislocation structures with the graphite, which disrupts normal lattice vibrations, and hence, the thermal conductivity of irradiated graphite is reduced substantially (by up to two orders of magnitude).

### 3.24.5.2 Enhanced Radiolytic Oxidation

In graphite-moderated, carbon dioxide-cooled nuclear power reactors,  $\gamma$ -irradiation modifies the chemistry of the reaction between graphite and  $\text{CO}_2$ . This takes the form of a radiolytic decomposition<sup>31</sup> of carbon dioxide to carbon monoxide and an oxygen radical as follows:

Although this decomposition is only transient because of the back reaction, the generation of gas-phase oxygen radicals (and related oxidizing species) is significant enough to comprise the major in-reactor oxidative degradation process for nuclear graphite. As the oxidation of small amounts of graphite can lead to relatively large reductions in mechanical properties, it is important to limit this process as much as possible. In practice, this is achieved in a number of ways. First, the addition of 1–1.5% of carbon monoxide into the coolant tends to scavenge the oxygen radicals produced in the gas-phase, although this process becomes less efficient above 1.5% CO. Thus, in order to maintain long-term integrity of the graphite moderator core, smaller amounts of methane and hydrogen are also added. The former decomposes within the graphite structure to form a sacrificial carbon layer, while the addition of hydrogen limits significant carbon deposition on the fuel rods (which would reduce the reactor efficiency).

### 3.23.1 Introduction

Metal–matrix composites (MMCs) are metals that are reinforced with either continuous or discontinuous constituents usually in the form of fibers (F), monofilaments (MF), particles (P), whiskers (W), or short fibers (SF). The reinforcements can be metals (e.g., tungsten), nonmetals (e.g., carbon, silicon), or ceramics (e.g., silicon carbide, boron carbide, or alumina). The selection of the matrix metal and reinforcement constituent is usually based on how well the combination interacts to achieve the desired properties. MMCs are usually stiff, strong, and lightweight, but they are also engineered for other properties. Reinforcements have been used in MMCs to increase stiffness,<sup>1</sup> strength,<sup>1</sup> thermal conductivity,<sup>2</sup> neutron shielding, and vibration damping capacity; and to reduce weight,<sup>1</sup> thermal expansion,<sup>3</sup> friction,<sup>4</sup> and wear.<sup>5</sup> Some, but not all, MMC properties are governed by the rule of mixtures.<sup>6</sup> Although MMCs

have properties more useful than those of their individual constituents, resistance to corrosion is usually sacrificed. The corrosion behavior of MMCs is often significantly different from that of their monolithic matrix alloys because of the presence of the reinforcements that alter the microstructure, electrochemical properties, and corrosion morphology.

The different types, typical applications, corrosion characteristics, and corrosion protection of MMCs will be summarized below.

### 3.23.2 Types of MMCs

A variety of MMCs have been developed with matrices such as aluminum, magnesium, lead, depleted uranium, stainless steel, titanium, copper, and zinc. Only MMCs with aluminum matrices, however, are extensively available.<sup>3</sup> Reinforcement constituents for MMCs include boron (B), graphite (Gr), silicon (Si), silicon carbide (SiC), boron carbide (B<sub>4</sub>C), titanium diboride (TiB<sub>2</sub>), alumina (Al<sub>2</sub>O<sub>3</sub>), mica, quartz, tungsten, yttria, and zircon. The reinforcement constituents usually range from 10 to 60 vol.%.

In this chapter, the MMC types will be denoted as matrix type/reinforcement composition/vol.% reinforcement type. Hence, aluminum/Al<sub>2</sub>O<sub>3</sub>/50 P MMC denotes an aluminum matrix MMC reinforced with 50 vol.% of Al<sub>2</sub>O<sub>3</sub> particles.

#### 3.23.2.1 Continuous-Reinforced MMCs

Continuous-reinforced (CR) MMCs are reinforced with continuous fibers or MF generally resulting in anisotropic properties, with substantial enhancements in the longitudinal direction of the reinforcement. The reinforcement diameter generally varies from 10  $\mu\text{m}$  for fibers (Figure 1(a)) to 150  $\mu\text{m}$  for MF (Figure 1(b)). Continuous reinforcements are usually much more

**Figure 1** Micrographs of (a) pure Al/Al<sub>2</sub>O<sub>3</sub>/50 F MMC (courtesy of J. Zhu) and (b) Ti-6Al-4V/SiC/MF MMC (courtesy of R. Srinivasan).

expensive than their discontinuous counterparts. Fabrication costs of CR MMCs are also higher than that of discontinuous-reinforced (DR) MMCs.

### 3.23.2.2 Discontinuous-Reinforced MMCs

DR MMCs are reinforced with particles, whiskers, or SF, and generally have isotropic properties and lower material and fabrication costs as compared to CR MMCs. Enhancements in properties of DR MMCs, however, are usually modest in comparison to CR MMCs. Reinforcement volume percents range from ~15 to 25% for structural MMCs (Figure 2(a)), and greater than 30% for MMCs used in electronic packaging (Figure 2(b)). Uniform particle and particle-size distribution are preferred in structural MMCs for optimal mechanical properties. In electronic-grade MMCs, the particle and particle-size distribution may not be uniform in order to maximize the reinforcement volume fraction. The high reinforcement loading in electronic-grade MMCs is necessary to reduce the coefficient of thermal expansion (CTE) to levels closer to that of electronic materials such as silicon and gallium arsenide.

### 3.23.3 MMC Applications

MMCs are being used in the aerospace, automotive, electronics, utilities, sports, and defence industries.

#### 3.23.3.1 Examples of Applications for CF MMCs

Aluminum/B/MF MMCs have been used for structural tubes in the space shuttle, resulting in 44% reduction in weight over aluminum alloys in the

original design.<sup>7</sup> Aluminum/Gr/F MMCs, which have unique properties such as negative to near-zero CTE, have been used as antenna booms in the Hubble Space Telescope.<sup>3</sup> In the automotive industry, Al/Al<sub>2</sub>O<sub>3</sub>/F MMCs have been used to replace cast iron components. Al/Al<sub>2</sub>O<sub>3</sub>/F MMCs with low weight, high temperature tensile and fatigue strengths, low thermal conductivity and expansion, and superior wear resistance are used in engine blocks, pistons, and cylinder heads.<sup>8</sup> Other types of Al/Al<sub>2</sub>O<sub>3</sub>/F MMCs with low weight, high strength, and high damping capacity are used for automotive push rods, resulting in increased horsepower generation.<sup>9</sup> These Al/Al<sub>2</sub>O<sub>3</sub>/F MMCs are also used as load-carrying core wires in high-current capacity and low-sag aluminum conductor cables (Figure 3). The Al/Al<sub>2</sub>O<sub>3</sub>/F MMCs core wires impart desirable properties to the cable such as high strength at ambient and elevated temperatures, low CTE, and lightweight.

#### 3.23.3.2 Examples of Applications for DR MMCs

Aluminum/SiC/20 P MMCs were used to replace aluminum tubes in the catamaran 'Stars and Stripes '88,' resulting in 20 wt% savings in comparison with monolithic aluminum.<sup>3</sup> Aluminum/Si/43 P MMCs, which are machinable, lightweight, and possess a low CTE, are used for electronic packaging (Figure 4(a)). For thermal management applications, copper-matrix MMCs are reinforced with milled graphite fibers that have negative CTEs and thermal conductivities exceeding that of copper. Accordingly, the resulting Cu/Gr MMCs have lower CTEs and higher thermal conductivity than copper.<sup>10</sup> In the automotive sector, DR MMCs are used for engine

**Figure 2** Micrographs of (a) Al 6092/SiC/10 P-T6 MMC and (b) Al 6092/SiC/50 P-T6 MMC. Courtesy of G. Hawthorn.

pistons, piston connection rods, rear wheel driveshafts, break calipers, cylinder liners, push rods, rocker arms, and valve guides.<sup>11</sup> DR MMCs are also used in the sports industry for high-performance bicycle frames and components, golf clubs, and baseball bats.<sup>11</sup> In the aircraft industry, examples of DR MMCs' used are fan exit guide vanes in turbine engines, ventral fins, helicopter blade sleeves (**Figure 4(b)**), and fuel access covers.<sup>12</sup> Other potential emerging applications for DR MMCs are shoes for tracked vehicles and light-weight armor.

### 3.23.4 Corrosion Characteristics

The presence of the reinforcements and the processing associated with MMC fabrication can lead to accelerated corrosion of the metal matrix. Special concerns regarding corrosion become important in MMCs as compared to the corrosion of the monolithic matrix alloys. Accelerated corrosion in MMCs

may originate from electrochemical, chemical, and physical interaction between MMC constituents because of their intrinsic properties or those induced by processing. Galvanic interaction between the reinforcement, matrix, and interphases can accelerate corrosion. Interphases and reinforcements may undergo chemical degradation, which is not electrochemical in nature. The microstructure of MMCs can influence corrosion by inducing segregation, intermetallic formation, and dislocation generation. Processing deficiencies may result in unexpected forms of corrosion.

The parameters affecting MMC corrosion that will be discussed are (1) electrochemical effects related to the primary MMC constituents; (2) electrochemical effects of the interphases; (3) chemical degradation in MMCs; and (4) secondary effects caused by the microstructure and processing. Corrosion in selected environments and corrosion protection will also be covered.

#### 3.23.4.1 Electrochemical Effects Related to the Primary MMC Constituents

Galvanic corrosion between the matrix and reinforcements is one of the primary concerns regarding the corrosion behavior of MMCs. Depending on the electrochemical properties of the MMC constituents, the galvanic corrosion rate can be controlled by either the anodic or cathodic reaction, or by both. Anodic control prevails when the cathodic reaction is depolarized (**Figure 5(a)**); cathodic control prevails when the anodic reaction is depolarized (**Figure 5(b)**); and there is mixed control when both the anodic and cathodic reactions polarize (**Figure 5(c)**).<sup>13</sup> For a galvanic couple with equal matrix and reinforcement

**Figure 3** Aluminum conductor composite reinforced cable specimen. Notice the seven inner Al/Al<sub>2</sub>O<sub>3</sub>/F MMC core wires.

**Figure 4** (a) Pure Al/Si/43 P MMC electronic package, and (b) 2009 Al/SiC/15 P-T4 helicopter blade sleeves (courtesy of DWA Aluminum Composites).

**Figure 5** Polarization diagrams showing (a) anodic control, (b) cathodic control, and (c) mixed control in galvanic corrosion.

area fractions, the intersection of the anodic polarization curve of the matrix metal and the cathodic polarization curve of the reinforcement indicates the magnitude of the galvanic corrosion current density ( $i_{\text{GALV}}$ ) (Figure 6). Hence, the degree of galvanic corrosion depends on the environment, matrix alloy, reinforcement electrochemistry, resistivity, and area fraction.

#### 3.23.4.1.1 Environment

The environment has a significant effect on galvanic corrosion rates. The two most primary factors are

usually dissolved-oxygen content and electrolyte composition (e.g., presence of aggressive ions).

In deaerated environments, the governing cathodic reaction for corrosion is hydrogen evolution:

In aerated solutions, oxygen reduction can also operate, and generally results in higher corrosion rates:

For example, if pure magnesium is coupled to an equal area of SiC MF with the ends exposed ( $\text{SiC}_{\text{MF}}^{\text{E}}$ ), the galvanic corrosion rate between Mg and  $\text{SiC}_{\text{MF}}^{\text{E}}$  would increase by  $\sim 4$  times if the solution is oxygenated (Figure 6). Interestingly, the normal corrosion rate of uncoupled pure magnesium does not significantly change in the presence of dissolved oxygen<sup>14</sup> since hydrogen evolution is the governing cathodic reaction for magnesium, as exemplified in Figure 6. Hence, it is important to recognize that the corrosion behavior and trends of the MMC could be significantly different than that of the monolithic matrix alloy.

The presence of aggressive ions can greatly increase the corrosion rate, especially for alloys to lose passivity. For example, the galvanic corrosion rate between a passive metal matrix and conductive reinforcements would be limited to the passive current density (CD), as demonstrated with the polarization diagram Al 6061-T6 plotted with those of various reinforcements in aerated chloride-free 0.5 M  $\text{Na}_2\text{SO}_4$  (Figure 7). In the presence of aggressive ions that breakdown passivity, the galvanic corrosion rates can dramatically increase (Figure 7). Using Al 6061-T6 coupled to an equal area of P100 graphite fibers with the ends exposed ( $\text{P100 Gr}^{\text{E}}$ ) as an example, the galvanic corrosion rate increases  $\sim 300$  times in aerated 3.15 wt% NaCl as compared to that in aerated 0.5 M  $\text{Na}_2\text{SO}_4$  (Figure 7).

#### 3.23.4.1.2 Matrix metal

Galvanic corrosion in MMCs reinforced with conductive, noble reinforcements is a concern in environments in which the matrix metal corrodes actively. For example, for MMCs reinforced with an equal area fraction of graphite fibers,  $i_{\text{GALV}}$  in aerated 3.15 wt% NaCl (Figure 8) would be only  $5 \times 10^{-7} \text{ A cm}^{-2}$  for Ti-15V-3Cr-3Sn-3Al (Ti-15-3), 1.5 orders of magnitude larger for pure copper ( $10^{-5} \text{ A cm}^{-2}$ ), and 3 orders of magnitude larger for Al 6061-T6 ( $3 \times 10^{-4} \text{ A cm}^{-2}$ ). The passivity of Ti-15-3 prevents  $i_{\text{GALV}}$  from exceeding the passive-CD (Figure 8).

**Figure 6** A collection of anodic and cathodic polarization curves of Mg (99.95%) exposed to aerated (open circles) or deaerated (solid circles) 0.5 NaNO<sub>3</sub> at 30 °C, and cathodic polarization curves of SiC<sub>MF</sub><sup>E15</sup> exposed to deaerated or aerated 0.5 NaNO<sub>3</sub> at 30 °C. Scan rate = 0.1 mV s<sup>-1</sup>. Superscript E denotes MF ends were exposed.

**Figure 7** A collection of anodic polarization diagrams of Al 6061-T6<sup>16</sup> exposed to aerated 0.5 M Na<sub>2</sub>SO<sub>4</sub> or 3.15 wt% NaCl at 30 °C, and cathodic polarization diagrams of P100 Gr<sup>E</sup>,<sup>16</sup> hot-pressed (HP) SiC,<sup>16</sup> SiC<sub>MF</sub><sup>E15</sup> and Si,<sup>17</sup> TiB<sub>2</sub>, and B<sub>MF</sub><sup>E</sup> exposed to aerated 3.15 wt% NaCl at 30 °C. Scan rate = 0.1 mV s<sup>-1</sup>.

**Figure 8** Anodic polarization diagrams of Ti 15-3,<sup>18,19</sup> pure Cu (99.999%), and Al 6061-T6<sup>16</sup> in deaerated 3.15 wt% NaCl at 30 °C. Cathodic polarization diagram of P100 Gr fibers<sup>16</sup> in aerated 3.15 wt% NaCl at 30 °C. Scan rate = 0.1 mV s<sup>-1</sup>.

In the case of pure copper,  $i_{\text{GALV}}$  is about 1 order of magnitude less than the normal copper corrosion CD ( $10^{-4}$  A cm<sup>-2</sup>) in the aerated 3.15 wt% NaCl; hence, galvanic action would increase corrosion of copper, but not significantly.

### 3.23.4.1.3 Reinforcement electrochemistry

In cases where galvanic corrosion is under cathodic control, the type of reinforcement may have a significant effect on the rate of galvanic corrosion. For example, in aluminum MMCs, the galvanic corrosion rates between Al 6061-T6 and various reinforcements ranked from the highest to lowest in aerated 3.15 wt% NaCl is as follows (Figure 9): P100 Gr > carbon-cored SiC<sub>MF</sub><sup>E</sup> with ends exposed > tungsten-cored B<sub>MF</sub><sup>E</sup> with ends exposed > hot-pressed (HP) SiC > Si. It should also be noted that ceramic reinforcements may vary in purity and structure, and some reinforcements are in themselves composites. This leads to interesting electrochemical behavior. For example, SiC MFs have carbon-rich outer layers and carbon cores, and their polarization diagrams have a stronger resemblance to P100 Gr<sup>E</sup> than to HP SiC. The orientation of reinforcements may also affect electrochemical behavior. SiC MFs have carbon cores and B MFs have tungsten cores. The polarization behavior of the circumferential surface of the MFs are different compared with the behavior of the ends of the MFs that expose the carbon and tungsten cores (Figure 9 compares cathodic curves for SiC MF<sup>S</sup> versus SiC MF<sup>E</sup>, and B MF<sup>S</sup> versus B MF<sup>E</sup>).

Therefore, the composition of the reinforcement is important to the extent that it affects the kinetics of hydrogen evolution and oxygen reduction.

For reinforcements of very high resistivity, galvanic corrosion can also be limited by a large ohmic drop through reinforcement.

### 3.23.4.1.4 Reinforcement photoelectrochemistry

If the MMC reinforcements or constituents are semiconductors (SCs), galvanic currents between the matrix metal and SC could be suppressed or accelerated depending on whether the SC is n-type or p-type, respectively.<sup>22</sup>

#### n-Type SCs

An n-type semiconductor is photoanodic, and under illumination promotes photooxidation reactions. One such reaction is the oxidation of water. In the presence of moisture and illumination on MMCs that contain n-type SCs, photogenerated electrons could polarize the MMC to more negative potentials inducing cathodic protection (Figure 10).<sup>22</sup> While the MMC

**Figure 9** A collection of anodic polarization diagrams of ultrapure Al (99.999%),<sup>16</sup> Al 1100,<sup>17</sup> and Al 6061-T6<sup>16</sup> and cathodic polarization diagrams of P100 Gr<sup>E</sup>,<sup>16</sup> HP SiC,<sup>16</sup> SiC<sub>MF</sub><sup>E</sup>,<sup>20</sup> SiC<sub>MF</sub><sup>S</sup>,<sup>20</sup> Si,<sup>17</sup> B<sub>MF</sub><sup>E</sup>,<sup>21</sup> and B<sub>MF</sub><sup>S</sup>,<sup>21</sup> exposed to aerated 3.15 wt% NaCl at 30 °C. Scan rate = 0.1 mV s<sup>-1</sup>.

**Figure 10** Polarization diagrams showing the effect of an illuminated n-type semiconductor (SC) on the corrosion current density (CD) of the MMC matrix.

is under illumination,  $E_{\text{corr}}$  shifts from  $E_{\text{corr}}$  (dark) to  $E_{\text{corr}}$  (illum), and the dissolution from the matrix decreases from  $i_{\text{matrix}}$  (dark) to  $i_{\text{matrix}}$  (illum). Accordingly, during anodic polarization of Al 6092/Al<sub>2</sub>O<sub>3</sub>/20 P-T6 MMCs that were immersed in air-exposed 0.5 M Na<sub>2</sub>SO<sub>4</sub> solutions, anodic current densities increased sharply during illumination which were attributed to photoanodic currents generated by water oxidation on TiO<sub>2</sub> particles that were likely introduced with the Al<sub>2</sub>O<sub>3</sub> reinforcements.<sup>23</sup> The open-circuit potentials also decreased upon illumination. In these MMCs exposed to outdoors, corrosion films were also thinner on the topside of specimens exposed to sunlight as compared with the backside of the specimens not exposed to sunlight.<sup>24</sup> Interestingly, MMCs containing p-type SCs had thicker corrosion films on the sunlit surfaces as opposed to the shaded surfaces.<sup>24</sup>

#### p-Type SCs

A p-type SC is photocathodic and under illumination promotes photoreduction reactions. Depending on the electrolyte conditions, proton or oxygen reduction may be enhanced at the p-type semiconductor. In the presence of moisture and illumination on MMCs that contain p-type SCs, photoreduction causes cathodic current to increase, raising the corrosion potential and corrosion rates (Figure 11).<sup>22</sup> While the MMC is under illumination,  $E_{\text{corr}}$  shifts positive from  $E_{\text{corr}}$  (dark) to  $E_{\text{corr}}$  (illum), and the dissolution from the matrix increases from  $i_{\text{matrix}}$  (dark) to  $i_{\text{matrix}}$  (illum). Accordingly, during cathodic polarization of pure Al/Si/43 P MMCs<sup>25</sup> and various Al 6092/SiC/P-T6 MMCs<sup>22</sup> that were immersed in air-exposed 0.5 M Na<sub>2</sub>SO<sub>4</sub> solutions, cathodic current densities increased sharply during illumination, which were attributed to photocathodic currents on

**Figure 11** Polarization diagrams showing the effect of an illuminated p-type SC on the corrosion CD of the MMC matrix.

the Si or SiC particles. The open-circuit potentials also increased upon illumination.<sup>22</sup> In these MMCs exposed to outdoors, corrosion films were also thicker on the sunlit surfaces as opposed to the shaded surfaces.<sup>24</sup>

### 3.23.4.1.5 Reinforcement resistivity

Reinforcement materials generally fall into the categories: insulators, SCs, or conductors (Table 1). For reinforcements that are insulators, galvanic corrosion is not possible. For SCs, the degree of galvanic corrosion will be restricted by the magnitude of ohmic losses through the reinforcements. This is demonstrated<sup>21</sup> by plotting (Figure 12) the cathodic curve derived from the hydrogen evolution on P100 Gr<sup>26</sup> exposed to aerated 3.15 wt% NaCl at 30 °C and incorporating a term for hypothetical ohmic losses through the electrode (eqn [3]).

$$E_{\text{APPLIED}}(V_{\text{SCE}}) = -0.67 - 0.081 \times \log i + ipt \quad [3]$$

The ohmic loss term  $ipt$  corresponds to a planar electrode having a thickness  $t$  and resistivity  $\rho$ , and one-dimensional current flow through the thickness. Equation [3] was plotted for various resistivity values and an electrode thickness of 5  $\mu\text{m}$  with that of anodic polarization diagrams of copper, Al 6061-T6, ZE 41A Mg, and pure magnesium in 3.15 wt% NaCl. Notice the effect of ohmic losses on the cathodic polarization diagrams and decreasing galvanic current densities as the reinforcement resistivities increase (Figure 12). For example,  $i_{\text{GALV}}$  of Al 6061-T6 is  $\sim 10^{-4} \text{ A cm}^{-2}$  for an ohmic loss  $IR_1$  resulting from a reinforcement resistivity of  $10^7 \Omega \text{ cm}$ . The value of  $i_{\text{GALV}}$  reduces

to  $\sim 10^{-7} \text{ A cm}^{-2}$  when the ohmic loss is increased to  $IR_2$  by a reinforcement resistivity of  $10^{10} \Omega \text{ cm}$ . The effect of reinforcement resistivity on the galvanic corrosion rate is also dependent on the type of matrix metal. The limiting effect on galvanic corrosion rates on copper only manifests at very high reinforcement resistivities (e.g.,  $>10^7 \Omega \text{ cm}$  in Figure 12); whereas, effects are seen on Al 6061-T6, ZE 41A Mg, and magnesium at lower resistivities. Note that the  $i_{\text{GALV}}$  values correspond to galvanic couples having equal anode and cathode areas.

Figure 12 is based on a fixed electrode thickness, but note that the critical resistivity to limit the galvanic corrosion rate below a particular level is also dependent on the thickness of the reinforcement since the ohmic loss is equal to  $ipt$ . Hence, if ohmic losses are to limit galvanic corrosion, reinforcements having higher resistivity are needed as the thickness or particle size of the reinforcement decreases. For example, to maintain an ohmic drop of 0.5 V at a galvanic CD of  $10^{-4} \text{ A cm}^{-2}$ , a 50- $\mu\text{m}$  particle would need a resistivity of  $10^6 \Omega \text{ cm}$ ; whereas, a 5- $\mu\text{m}$  particle would need a resistivity of  $10^7 \Omega \text{ cm}$  to achieve the same ohmic loss. If the reinforcements that are used in MMCs are not of high purity, resistivities may drop significantly allowing galvanic corrosion to ensue. For example, Al/SiC MMCs are fabricated from both high-purity green SiC and lower-purity black SiC, depending on the application. The resistivity of SiC may vary by  $\sim 18$  orders of magnitude depending on its purity.<sup>27</sup> Boron MFs are more conductive than pure boron due to tungsten and tungsten borides in the core.<sup>28</sup> In fact, many

**Table 1** Resistivities of reinforcement materials

Material	Resistivity ( $\Omega \text{ cm}$ )	Temperature ( $^{\circ}\text{C}$ )	Notes	Ref.
$\text{Al}_2\text{O}_3$	$>10^{14}$	30	99.7% $\text{Al}_2\text{O}_3$	29

$\text{SiC}_{\text{MF}}^{\text{S}}$	$2 \times 10^{-2}$	25		
$\text{B}_{\text{MF}}^{\text{E}}$	$2 \times 10^{-1}$	25		
$\text{B}_{\text{MF}}^{\text{S}}$	$5 \times 10^{-1}$	25		

reinforcement materials have resistivities that are not high enough to stifle galvanic corrosion. The resistivities of some reinforcement materials are shown in [Table 1](#). The treatment above for the ohmic losses through reinforcement particles should only be considered as an approximation since one-dimensional current flow was assumed. In the actual case, the ohmic drop through the edges of the particle could be much less than through the thickness. The galvanic corrosion rate can also significantly increase as the area fraction of the reinforcements increases.

### 3.23.4.1.6 Reinforcement area fraction

The galvanic corrosion rate generally increases with the area fraction of the reinforcement. This is demonstrated ([Figure 13](#)) using the anodic polarization diagrams of copper, Al 1100, Al 6061-T6, pure

**Figure 12** Plots of the Tafel equation for oxygen reduction on P100 Gr<sup>E</sup> incorporating the effect of hypothetical ohmic losses based on various resistivities [eqn \[3\]](#) in aerated 3.15 wt% NaCl at 30 °C.<sup>21</sup> The anodic polarization diagrams of Cu, Al 6061-T6,<sup>16</sup> pure Mg, and ZE 41A Mg are also shown. The pure Mg and ZE41A Mg diagrams correspond to oxygenated solutions. Scan rate = 0.1 mV s<sup>-1</sup>.

**Figure 13** Anodic polarization diagrams of Cu, Al 1100, Al 6061-T6, Mg, and ZE 41A Mg, and cathodic polarization diagrams of P100 Gr<sup>E</sup> showing the effect of the P100 Gr<sup>E</sup> area fraction  $X_C$  on the galvanic current in aerated 3.15 wt% NaCl at 30 °C. Scan rate = 0.1 mV s<sup>-1</sup>.<sup>21</sup> The electrode area of the anodic diagrams corresponds to 1 cm<sup>2</sup>.

magnesium (99.95% metallic purity), and ZE 41A Mg, and the cathodic polarization diagram of P100 Gr.<sup>16</sup> The cathodic curve for P100 Gr<sup>E</sup> shifts to higher currents as its area fraction is increased, causing the galvanic current with the various metals and alloys to increase. Since the galvanic couples are predominately under cathodic control, the catchment area principle<sup>34</sup> can be used to determine  $i_{\text{GALV}}$  as a function of the area fraction of the cathodic reinforcement.<sup>16</sup>

$$i_{\text{GALV}} = i_C(X_C/1 - X_C) \quad [4]$$

The parameter  $i_{\text{GALV}}$  is the dissolution CD of the matrix (i.e.,  $i_{\text{GALV}}$ /anode area);  $i_C$  is the CD of the cathode;  $X_C$  is the area fraction of the cathode; and  $(1 - X_C)$  is the area fraction of the anode. The value of  $i_C$  can be set equal to the CD of the cathodic constituents at the galvanic couple potential. For example, the galvanic couple potentials of ultrapure aluminum, Al 1100, and Al 6061-T6 couple to various reinforcements are coincident with the pitting potentials of the aluminum alloys (i.e.,  $\sim -0.75$  V<sub>SCE</sub>). Hence, the values of  $i_C$  for a variety of reinforcements were read at  $\sim -0.75$  V<sub>SCE</sub> from [Figure 7](#). By plotting [eqn \[4\]](#), a graph ([Figure 14](#)) was generated from which  $i_{\text{GALV}}$  of ultrapure aluminum, Al 1100, or Al 6061-T6 can be obtained as a function of the area fraction of P100 Gr<sup>E</sup>, SiC MF<sup>E</sup>, B MF<sup>E</sup>, HP SiC, and Si with exposure to aerated 3.15 wt% NaCl at 30 °C.<sup>21</sup> [Figure 14](#) shows that to sustain a galvanic corrosion rate equal to the normal corrosion rate of Al 6061-T6, it would take less than 0.05 area fraction of P100 Gr<sup>E</sup> or SiC MF<sup>E</sup>, between 0.2 and 0.3 area fraction of B MF<sup>E</sup> and HP SiC, and more

**Figure 14** Graphs showing the galvanic corrosion current density  $i_{\text{GALV}}$  of ultrapure Al (99.999%), Al 1100, or Al 6061-T6 as a function of the area fraction  $X_C$  of P100 Gr<sup>E</sup>, SiC MF<sup>E</sup>, B MF<sup>E</sup>, HP SiC, and Si for exposure to aerated 3.15 wt% NaCl at 30 °C. The horizontal dashed lines represent the normal corrosion rates of ultrapure Al and Al 6061-T6. Reproduced from Hihara, L. H. *Corros. Rev.* **1997**, 15(3-4), 361.

**Figure 15** Graphs showing the galvanic corrosion current density  $i_{\text{GALV}}$  of pure Mg and ZE 41A Mg as a function of the area fraction  $X_C$  of P100 Gr<sup>E</sup>, SiC MFE, B MFE, HP SiC, and Si for exposure to aerated 3.15 wt% NaCl at 30 °C. The horizontal dashed lines represent the normal corrosion rates of pure Mg and ZE 41A Mg.

than 0.9 area fraction of Si. It should be noted that for those reinforcements for which  $i_C$  was read in the diffusion-limited regime for oxygen reduction, galvanic corrosion rates could increase with additional convection. A similar figure was developed for pure magnesium and ZE 41A Mg (Figure 15).

The above discussion did not take into consideration the distribution of the anodic and cathodic current densities over the MMC microstructure. In some cases, for very low levels of conductive particles, localized corrosion can be induced by solution alkalization, as will be discussed below.

### 3.23.4.1.7 Microstructure

The physical presence of the reinforcements also greatly affects MMC corrosion. The reinforcements, which are usually inert in comparison to the matrix, are often left in relief as the matrix corrodes leaving behind a network of fissures that trap corrosion products and exacerbate corrosion (Figure 16). The initiation and propagation of corrosion sites are generally influenced by the electrical resistivity and volume fraction of the MMC constituents, including the reinforcements, interphases, and intermetallics. The corrosion behavior of MMCs in the open-circuit condition can be quite different from what might be expected based on anodic polarization diagrams of the MMCs. For example, in near-neutral 0.5 M Na<sub>2</sub>SO<sub>4</sub> solutions, various aluminum MMCs passivate (Figure 17)<sup>35,36</sup> during anodic polarization, but in the open-circuit condition, the same MMCs are susceptible to localized corrosion. The localized corrosion in the open-circuit condition is caused by the development of localized anodic and cathodic

**Figure 16** SEM micrograph of region of localized corrosion on Al 6092/SiC/20 P-T6 MMC exposed for 24h in aerated 0.5 M Na<sub>2</sub>SO<sub>4</sub> at 30 °C in the open-circuit condition. Micrograph courtesy of H. Ding.

**Figure 17** Anodic polarization curves of various Al MMCs exposed to 0.5 M Na<sub>2</sub>SO<sub>4</sub> at 30 °C. Scan rates are 1 mV s<sup>-1</sup> (Al 6092-T6 MMCs) and 0.1 mV s<sup>-1</sup> (pure Al/Si/43 P MMC).

sites. The alkalinity in cathodic regions and acidity in anodic regions are accentuated by the formation of microcrevices in the network of reinforcement particles in relief. In the case of Al MMCs, aluminum loses its passivity in both the acidic and alkaline environments because of the amphoteric nature of aluminum oxide.

When an MMC is exposed to an electrolyte in the open-circuit condition, the sum of anodic current  $I_a$  is equal to the sum of cathodic current  $I_c$ :

$$I_a = I_c \quad [5]$$

Hence, the anodic and cathodic current densities are related by eqn [6],<sup>35</sup>

$$i_c = i_a \frac{(1 - x_c)}{x_c} \quad [6]$$

where  $i_c$  and  $i_a$  are the cathodic and anodic current densities, respectively, and  $x_c$  is the area fraction of cathodic constituents, here assumed to be conductive reinforcement, interphase, or intermetallic particles.

From eqn [6], the cathodic CD over cathodic constituents in the MMC microstructure can be approximated if the anodic CD of the matrix  $i_a$ , and the area fraction of cathodic constituents  $x_c$  are known. Experimental results on Al MMCs have indicated that the corrosion initiation sites depended on the amount of electrically conductive cathodic constituents that are present in the MMC microstructure. If the area fraction of cathodic constituents were low, corrosion initiated around the cathodic constituents because of solution alkalization; if the area fraction of cathodic constituents were high, corrosion initiation appeared more random around the reinforcement constituents.

Equation [6] was used to calculate the cathodic CD (Table 2) emanating from cathodic sites based on the area fraction  $x_c$ , and the assumption that the passive CD of the aluminum matrix was  $\sim 4 \times 10^{-6} \text{ A cm}^{-2}$ , based on the passive CD of various Al 6092-T6 MMCs (Figure 17). This passive CD should also be approximately equal to the initial anodic CD  $i_a$  of the Al matrix in the MMC at the open-circuit potential, prior to the development of significant pH gradients.

#### Low content of cathodic constituents

When the amount of cathodic sites is relatively low, cathodic current densities become concentrated over

the few cathodic sites resulting in hydroxide ion buildup. If the matrix material is not stable at high pH levels, localized corrosion can result. Table 2 shows the values of  $i_c$  as a function of  $x_c$ , assuming a value for  $i_a$  to be equal to  $4 \times 10^{-6} \text{ A cm}^{-2}$ , which is an estimate of the passive CD of an Al 6092-T6 matrix.

When values of  $x_c$  become less than  $\sim 0.04$  (Table 2), the cathodic current densities begin to exceed  $10^{-4} \text{ A cm}^{-2}$ , which can lead to solution alkalization by oxygen reduction and hydrogen evolution. Cathodic current densities of the order of  $10^{-4} \text{ A cm}^{-2}$  causes phenolphthalein dye in 0.5 M  $\text{Na}_2\text{SO}_4$  solutions to transform from clear to red for electrodes in quiescent solutions. The color change of phenolphthalein occurs in a pH range from 8.3 to 9.8. Aluminum corrosion rates increase exponentially when the pH exceeds  $\sim 8$ .<sup>37</sup> Hence, corrosion can be expected around cathodic constituents if their area fractions are low.

Accordingly, corrosion was observed on an Al 6092/ $\text{Al}_2\text{O}_3$ /20 P-T6 MMCs around intermetallic particles (Figure 18) in 0.5 M  $\text{Na}_2\text{SO}_4$ , in which Al passivates during anodic polarization.

In these MMCs, the  $\text{Al}_2\text{O}_3$  particles are insulators and cannot serve as cathodes; however, several types of particles, including titanium suboxides with compositions close to that of  $\text{Ti}_6\text{O}$ ,  $\text{Ti}_3\text{O}$ ,  $\text{Ti}_2\text{O}$ , and  $\text{TiO}$ ;  $\text{TiO}_2$  (likely doped); Ti–Zr–Al containing oxides; and Fe–Si–Al intermetallics<sup>23</sup> were found. Of these particles, the titanium suboxides,  $\text{TiO}_2$ , and the Fe–Si–Al intermetallics supported significant cathodic activity.<sup>23</sup> The area fraction of the non- $\text{Al}_2\text{O}_3$  particles in the MMCs was estimated to be of the order of 0.01 using image analysis.<sup>35</sup> Hence, if the area fraction of the cathodic constituents was less than 0.01, cathodic current densities in excess of  $10^{-4} \text{ A cm}^{-2}$  could result in significant solution alkalization and corrosion.

The scanning vibrating electrode technique (SVET) and scanning ion-selective electrode technique (SIET) revealed that localized corrosion over Al 6092/ $\text{Al}_2\text{O}_3$ /20 P-T6 MMCs immersed in 0.5 M  $\text{Na}_2\text{SO}_4$  was coinciding with that in alkaline, cathodic regions.<sup>38</sup>

The type of corrosion discussed above was suppressed in pH 7 buffered solutions. Only staining was observed around the intermetallics (Figure 19).

#### High content of cathodic constituents

MMCs that contain relatively high levels of cathodic sites should generally be more immune to corrosion

**Table 2** Values<sup>a</sup> of  $i_c$  as a function of  $x_c$

$i_c \text{ (A cm}^{-2}\text{)}$	$x_c$
$4 \times 10^{-3}$	0.001
$4 \times 10^{-4}$	0.01
$1 \times 10^{-4}$	0.04
$4 \times 10^{-5}$	0.1
$2 \times 10^{-5}$	0.2
$9 \times 10^{-6}$	0.3
$4 \times 10^{-6}$	0.5

<sup>a</sup> $i_c$  values correspond to  $i_a = 4 \times 10^{-6} \text{ A cm}^{-2}$ .

**Figure 18** Virgin Al 6092/Al<sub>2</sub>O<sub>3</sub>/20 P-T6 MMC (a) and after 2 days of immersion (b) in air-exposed 0.5 M Na<sub>2</sub>SO<sub>4</sub> at 30 °C. Intermetallic particles appear as light gray, and Al<sub>2</sub>O<sub>3</sub> appears as near black.

**Figure 19** Al 6092/Al<sub>2</sub>O<sub>3</sub>/20 P-T6 MMC in the virgin state (a) and after immersion for 17 days in air-exposed pH 7 buffered solution at 30 °C (b). Notice staining of the matrix around the intermetallic particle, but lack of localized corrosion.

**Figure 20** Al 6092/SiC/40 P-T6 MMC in the virgin state (a) and after immersion for 2 days (b) in air-exposed 0.5 M Na<sub>2</sub>SO<sub>4</sub> at 30 °C.

initiation caused by extensive hydroxide ion buildup around the cathodic constituents, since the cathodic current is dispersed over more sites.

For example, in Al MMCs that are exposed to Na<sub>2</sub>SO<sub>4</sub> solutions in which the Al matrix passivates, the cathodic current densities are estimated to be relatively low (i.e.,  $\leq 4 \times 10^{-5} \text{ A cm}^{-2}$ ) (Table 2) for  $x_c$  greater than  $\sim 0.1$ . Accordingly, corrosion initiation

sites on Al 6092-T6 MMCs reinforced with semiconductive SiC (Figure 20) and B<sub>4</sub>C (greater than 10 vol. %) were different in appearance from the alkali-induced corrosion around intermetallics (Figure 18) in the Al 6092/Al<sub>2</sub>O<sub>3</sub>/20 P-T6 MMC.<sup>35</sup>

One possible source of the corrosion initiation sites on the Al 6092-T6 MMCs reinforced with SiC or B<sub>4</sub>C could be the formation of crevices at SiC–Al

or  $B_4C$ –Al interfaces by the hydrolysis of  $Al_4C_3$ , which is a reaction product of SiC and Al<sup>39</sup>, and  $B_4C$  and Al.<sup>40</sup>  $Al_4C_3$  readily hydrolyses upon contact with moisture and could leave fissures in the SiC–aluminum and  $B_4C$ –aluminum interface (see Section 3.23.4.3).

Once a crevice is formed at the particle–matrix interface, crevice corrosion can ensue. If the reinforcement particles are electrically conductive, they can serve as cathodic sites for hydrogen and/or oxygen reduction. As a result, for Al MMCs, the environment in the crevice will become acidic:

The acidified solution in the crevice can breakdown passivity because of the amphoteric nature of  $Al_2O_3$  and exacerbate corrosion. Eventually, corrosion spreads and encompasses adjacent particles forming a network of microcrevices caused by reinforcement particles in relief (Figures 21). The solution above the network of microcrevices has been measured to be acidic in the initial stages of growth.<sup>38</sup> The region around the centralized anodic region becomes alkaline because of the reduction of oxygen in surrounding regions.<sup>38</sup>

### 3.23.4.2 Electrochemical Effects of the Interphases

During the fabrication processing of MMCs, reactions between the reinforcement and matrix may lead to the formation of an interphase at the reinforcement–matrix interface. The presence of the interphase may lead to corrosion behavior different from what might

be expected based on virgin MMC constituents. For example, Pohlman<sup>41</sup> could not measure galvanic currents between virgin B MFs and Al 2024 or Al 6061 in 3.5% NaCl solutions, indicating that galvanic corrosion between aluminum matrices and B MFs should be negligible. In actual Al/B/MF MMCs, however, galvanic corrosion takes place between the aluminum matrix and the aluminum boride interphase on the surface layers of the B MFs.<sup>41</sup> Pohlman measured galvanic currents between the aluminum alloys and B MFs that were extracted from the matrix. A 4- $\mu m$ -thick layer of aluminum boride enveloped the extracted B MFs. Galvanic currents measured between the aluminum alloys and aluminum boride were similar to those between the alloys and the extracted B MFs. When the layer of aluminum boride was removed from the extracted B MFs, the galvanic current ceased, which indicated that the aluminum boride interphase was necessary for galvanic corrosion.

### 3.23.4.3 Chemical Degradation in MMCs

MMCs may also degrade by chemical reactions that cannot be directly assessed by electrochemical measurements. Interphases and reinforcement phases may undergo chemical degradation which cannot be detected, for example, with the aid of anodic polarization. In aluminum MMCs, the hydrolysis of the  $Al_4C_3$  interphase is one such example. Aluminum carbide degradation can affect Al/Gr, Al/SiC, and Al/ $B_4C$  MMCs. Reinforcement phases may also experience degradation. For example, mica particles have been reported to undergo exfoliation in Al/mica MMCs.

**Figure 21** Al 6092/SiC/20 P-T6 MMC in air-exposed 0.5 M  $Na_2SO_4$  (a), and pH profile over the specimen (b). Notice acidification of localized corrosion sites, and the alkalinization of surrounding cathodic sites.

### 3.23.4.3.1 Aluminum carbide hydrolysis

Aluminum carbide forms by the reaction of aluminum and carbon,<sup>42</sup>

and its formation is substantial in Al/Gr MMCs during processing if temperatures are significantly higher than the liquidus temperature. At lower temperatures,  $\text{Al}_4\text{C}_3$  formation can be controlled.<sup>43</sup>

Aluminum carbide also forms by the reaction of aluminum and SiC,

and has been found at SiC–Al interfaces if the Si activity in liquid aluminum is low.<sup>39</sup>

The formation of  $\text{Al}_4\text{C}_3$  by the reaction of Al and  $\text{B}_4\text{C}$  is reported to occur rapidly at 900 °C. In addition, many other Al–B–C compounds are known to form.<sup>40</sup>

In the presence of moisture,  $\text{Al}_4\text{C}_3$  hydrolyzes to liberate methane gas by the reaction

Methane evolution has been detected from Al/Gr MMCs containing  $\text{Al}_4\text{C}_3$ .<sup>44,45</sup> The rate of  $\text{Al}_4\text{C}_3$  hydrolysis was measured to be ~1% per hour for HP  $\text{Al}_4\text{C}_3$  (78% of theoretical density and porous) exposed to pure water at 30 °C.<sup>26</sup> Buonanno<sup>45</sup> reported that  $\text{Al}_4\text{C}_3$  hydrolysis in Al/Gr MMCs leaves fissures at fiber–matrix interfaces. The hydrolysis of  $\text{Al}_4\text{C}_3$ , therefore, could result in rapid penetration into the MMC microstructures through fiber–matrix interfaces, and lead to the formation of microcrevices at reinforcement–matrix interfaces.

### 3.23.4.3.2 Mica degradation

Muscovite mica  $\text{KAl}_3\text{Si}_3\text{O}_{10}(\text{OH})_2$  particles of ~70  $\mu\text{m}$  in size<sup>46</sup> have been used in Al MMCs developed for potential use in applications where good antifriction, seizure resistance, and high-damping capacity are required.<sup>47</sup> During exposure to nonde-aerated 3.5 wt% NaCl solutions, the mica particles appeared to have absorbed moisture, swelled, and then exfoliated.<sup>48</sup>

### 3.23.4.4 Secondary Effects

The presence of the reinforcement phases in the MMCs may alter the microstructural features in the matrix material in ways that are nonexistent in the monolithic matrix alloys. Two examples that are discussed here are

the formation of intermetallic phases around reinforcements by solute rejection during solidification,<sup>49</sup> and the mismatch in the CTE between reinforcements and matrices that can lead to dislocation generation,<sup>50</sup> which potentially could lead to higher corrosion in some metals.<sup>51</sup>

### 3.23.4.4.1 Intermetallics

Intermetallics may have potentials and corrosion resistance different from that of the matrix. Table 3 shows corrosion potentials, pitting potentials, and normal corrosion current densities of various metals and intermetallics.<sup>52</sup> Noble and inert intermetallics may induce galvanic corrosion of the matrix; whereas, active intermetallics may go into dissolution and leave fissures or crevices.

In Al/ $\text{Al}_2\text{O}_3$  MMCs,  $\text{Al}_8\text{Mg}_5$  and  $\text{Mg}_2\text{Si}$ , intermetallics provided corrosion paths along fiber–matrix interfaces.<sup>53</sup> Pits in Al/ $\text{Al}_2\text{O}_3$  MMCs exposed to NaCl solutions containing  $\text{H}_2\text{O}_2$  were attributed to the dissolution of  $\text{MgAl}_3$ , which is rapidly attacked at low potentials.<sup>54</sup> In Al/mica MMCs, a dendritic

**Table 3** Corrosion data<sup>a</sup> of intermetallics

phase, which was probably  $\text{Mg}_2\text{Al}_3$  or  $\text{Al}_8\text{Mg}_5$ , and spheroidized  $\text{CuMgAl}_2$  were preferentially attacked in nondeaerated 3.5 wt%  $\text{NaCl}$ .<sup>55</sup>

#### 3.23.4.4.2 Dislocation density

The high strengths of particulate MMCs in comparison to their monolithic alloys are generated by high dislocation densities caused by a mismatch in the CTE between reinforcement and matrix, and heating and cooling histories.<sup>50</sup> Since cold working, which is the result of generating high dislocation densities, is known to change the corrosion behavior of metals such as steel<sup>51</sup> and aluminum,<sup>56</sup> the corrosion behavior of MMCs may also be affected by high dislocation densities.<sup>21</sup> It has been suggested that corrosion near the  $\text{SiC}$ - $\text{Al}$  interface in  $\text{Al/SiC}$  MMCs could be caused by high dislocation density because of a mismatch of the CTE between  $\text{SiC}$  and  $\text{Al}$ .<sup>57,58</sup>

#### 3.23.4.4.3 MMC processing

Processing-induced corrosion is not inherently caused by the primary components of the MMC system, but results from processing deficiencies. The corrosion of diffusion bonds in  $\text{Al/B}$  MMCs and corrosion due to microstructural chlorides in some  $\text{Al/Gr}$  MMCs are two examples.

#### Low-integrity diffusion bonds

The open-circuit potentials of  $\text{Al}$  MMCs reinforced with  $\text{B}$  MFs were active as that of their monolithic matrix alloys in aerated  $\text{NaCl}$  solutions,<sup>59,60</sup> which were not expected since  $\text{B}$  MFs had open-circuit potentials that were noble to that of the monolithic matrix alloy. On the basis of the mixed-potential theory, it was expected that the MMCs would equilibrate at potentials between that of the noble  $\text{B}$  MF and the monolithic matrix alloy. To investigate the origin of this discrepancy, Bakulin *et al.*,<sup>60</sup> measured the open-circuit potentials of HP stacks of aluminum foil processed in the same way as the MMC (but without the  $\text{B}$  MFs), and found that the HP aluminum stacks were active as that of the monolithic alloy as well as the MMCs. The only difference between the HP stacks of aluminum foil and the monolithic aluminum was crevices in the diffusion bonds between adjacent foils which served as additional anodic sites.

#### Microstructural chlorides

Some types of  $\text{Al 6061/Gr/50 F-T6}$  MMCs were found to have been contaminated with microstructural chlorides during processing<sup>61</sup> by the  $\text{Ti-B}$  vapor

deposit method<sup>62</sup> that utilizes  $\text{TiCl}_4$  and  $\text{BCl}_3$  gases. The presence of microstructural chlorides in the  $\text{Al/Gr}$  MMCs was confirmed during microstructural analyses, and the effect of the chlorides was evident in anodic polarization diagrams.<sup>63</sup> These MMCs are pitted at  $\sim -0.6 \text{ V}_{\text{SCE}}$  in 0.5 M  $\text{Na}_2\text{SO}_4$ <sup>63</sup>; whereas, both the matrix alloy and other types of  $\text{Al/Gr}$  MMCs are processed by pressure infiltration without the use of chlorides passivate in 0.5 M  $\text{Na}_2\text{SO}_4$ .<sup>45</sup> The residual microstructural chlorides also make these MMCs inherently unstable, and as a result, some specimens have suffered from corrosion initiating subcutaneously beneath monolithic  $\text{Al}$  skins after long storage in laboratory air (Figure 22). This type of subcutaneous corrosion has also been observed in a similar type of  $\text{Mg/Gr}$  MMC (Figure 23).

#### 3.23.4.5 Corrosion in Environments

A comprehensive study of  $\text{Al 6092-T6}$  MMCs reinforced with black  $\text{SiC}$  (5, 10, 20, 40, and 50 vol%), green (high purity)  $\text{SiC}$  (50 vol%),  $\text{B}_4\text{C}$  (20 vol%), and  $\text{Al}_2\text{O}_3$  (20 vol%) has been examined in a battery of immersion, humidity-chamber exposure, and outdoor exposure tests.<sup>64</sup> The wide range of reinforcement types and testing conditions allows trends in corrosion behavior to be made and will be

**Figure 22** Subcutaneous corrosion in  $\text{Al/Gr}$  MMC with over 10 years exposure in laboratory air.

**Figure 23**  $\text{Mg/Gr}$  MMC showing subcutaneous corrosion after more than 15 years in storage.

highlighted here. Since galvanic corrosion between the Al 6092-T6 matrix and reinforcement particles depends on the ability of the particle to conduct electricity, the electronic resistivities of the particle should have an effect on the corrosion behavior. The resistivity of  $B_4C$  is  $\sim 10^0 \Omega \text{ cm}$ ,<sup>32</sup> that of SiC ranges from  $\sim 10^{-5}$  to  $10^{13} \Omega \text{ cm}$  depending on its purity,<sup>27</sup> and that of  $Al_2O_3$  is  $10^{14} \Omega \text{ cm}$ .<sup>29</sup> The green SiC possessing high electrical resistivity should be less likely to promote galvanic corrosion of the aluminum matrix as compared to black SiC, which is of lower purity and resistivity.

### 3.23.4.5.1 Immersion exposure

Immersion studies were conducted for 90 days in 3.15 wt% NaCl, ASTM seawater, real seawater, 0.5 M  $Na_2SO_4$ , and ultrapure 18  $\Omega \text{ cm}$  water exposed to air at 30 °C. The dimensions of the specimens were  $\sim 2.54 \text{ cm} \times 2.54 \text{ cm} \times 0.25 \text{ cm}$ . Specimens in triplicate were examined, but data correspond to results from two specimens for each testing condition (Figure 24). The third specimen was reserved for further surface analyses.

Corrosion rates were generally highest for the MMCs immersed in 3.15 wt% NaCl. The rates were much lower in ASTM seawater because of the formation of a film on the MMC surfaces, which was likely composed of Al–Mg hydrotalcite-like compounds.<sup>65</sup> The film may have impeded the diffusion of dissolved oxygen to cathodic regions limiting the corrosion rate. For most of the specimens, the

corrosion rates in  $Na_2SO_4$  were similar to those in NaCl. Although Al MMCs generally passivate in  $Na_2SO_4$  solutions during anodic polarization, they corrode in the open-circuit condition because of the formation of localized acidic and alkaline regions (see Section 3.23.4.1.7).

Most of the trends observed in the corrosion rate versus the reinforcement composition and type indicated that the level of galvanic corrosion between the matrix and reinforcements increases as the reinforcement electrical resistivity decreases, and as the reinforcement content increases. For the MMCs with 20 vol% of particulates, the corrosion rates were generally highest for that reinforced with  $B_4C$ , followed by that with black SiC, and least for that with  $Al_2O_3$ . Of the three types of reinforcements, the  $B_4C$  has the lowest electrical resistivity, and  $Al_2O_3$  has the highest. For the MMCs reinforced with 5, 10, 20, 40, and 50 vol% black SiC, the corrosion rates also generally increased as the volume fraction increased. For the MMCs reinforced with 50% black or green SiC, corrosion rates were higher for those that were reinforced with the lower purity, more conductive, black SiC in ASTM seawater and 0.5 M  $Na_2SO_4$ . It was expected that this trend would also be observed for the 3.15 wt% NaCl solution, but the results in this solution were skewed because of crevice and localized corrosion on one of the MMCs reinforced with the higher-purity, less-conductive, green SiC. A crevice formed on the specimen because of contact with the specimen holder, and a highly localized corrosion

**Figure 24** Corrosion rates of Al 6092-T6 MMCs under immersion conditions in air-exposed solutions for 90 days at 30 °C. Reproduced from Hawthorn G. A. MS Thesis, University of Hawaii at Manoa, Honolulu, 2004.

site formed in a region of high plastic deformation where the specimen was stamped for identification.

### 3.23.4.5.2 Humidity chamber exposure

Humidity chamber studies were conducted for 90 days at 85% RH (relative humidity) and 30 °C. The dimensions of specimens were  $\sim 2.54 \text{ cm} \times 2.54 \text{ cm} \times 0.25 \text{ cm}$ . The specimens were treated in 3.15 wt% NaCl, ASTM seawater, actual seawater, and 0.5 M  $\text{Na}_2\text{SO}_4$  by immersion in the electrolyte for 1 min, air-dried, and then placed in the humidity chamber. Specimens in triplicate were examined, but data correspond to results from two specimens for each testing condition (Figure 25). The third specimen was reserved for further surface analyses.

The corrosion rates of specimens treated with ASTM seawater were generally comparable to or exceed those treated with NaCl, as the hydrotalcite-like films cannot form in the absence of an electrolyte. The specimens treated with  $\text{Na}_2\text{SO}_4$  generally had the lowest corrosion rates. Corrosion rates also generally increased for the MMCs reinforced with black SiC as the SiC content increased. For the MMCs reinforced with 50 vol% SiC, corrosion rates were lower for those having the high-purity, higher resistivity, and green SiC.

### 3.23.4.5.3 Outdoor exposure

The MMC specimens were exposed to six outdoor sites. The specimens were  $\sim 9 \text{ cm}$  in diameter and

2.5 mm in thickness. Specimens in triplicate were examined, but data correspond to results from two specimens for each testing condition (Figure 26). The third specimen was reserved for further surface analyses.

The test sites were industrial (Campbell Industrial Park), agricultural (Ewa Nui), arid (Waipahu), marine (Kahuku and Coconut Island sites), and rain forest (Lyon Arboretum). Weather and environmental data are provided for the 180-day exposure period (Table 4).

Some trends are clearly visible in the corrosion data (Figure 26). The corrosion rates of the MMCs reinforced with black SiC generally increased with an increase in volume fraction of the reinforcement. This would be expected due to galvanic action between the black SiC and aluminum matrix. For the MMC reinforced with 50 vol% SiC, those having the black SiC corroded at higher rates than those reinforced with the high-purity, higher-resistivity, and green SiC. For the three types of MMCs with 20 vol% particulates, those reinforced with  $\text{B}_4\text{C}$  generally corroded at a higher rate than those reinforced with less-conductive SiC or  $\text{Al}_2\text{O}_3$ .

The highest corrosion rates were generally observed at the Manoa (very wet), Coconut Island (marine), and Kahuku (marine) test sites. The high corrosion rate at Manoa is likely due to persistent rain since chloride levels are negligible at that site.

**Figure 25** Corrosion rates of Al 6092-T6 MMCs treated with various salts and exposed to 85% RH for 90 days at 30 °C. Reproduced from Hawthorn G. A. MS Thesis, University of Hawaii at Manoa, Honolulu, 2004.

### 3.23.5 Corrosion Protection of MMCs

Corrosion of metals can be prevented with the use of protective coatings and inhibitors. The type of coating (e.g., impervious, inhibitive, or cathodically protective) will depend on the application; for example, immersion or atmospheric exposure. For MMCs, however, a proven coating system for the matrix alloy may not be suitable. Poor adhesion and wettability between the coating and reinforcement or differences in the electrochemical properties of the alloy and the MMC may render a good coating system for the ineffectiveness of alloy for the MMC. Other coating techniques such as anodization could also be ineffective or even deleterious to the MMC. Various studies on the corrosion protection of MMCs utilizing

organic coatings, inorganic coatings, anodization, chemical conversion coatings, and inhibitors have been summarized elsewhere.<sup>66</sup>

### 3.23.6 Conclusions

The corrosion of MMCs is significantly more complicated and less predictable than that of their monolithic alloys. MMC systems that consist of active metal matrices and noble reinforcements have inherent galvanic corrosion problems. Some systems, such as those containing aluminum and carbon, may also be susceptible to interphase formation of the deleterious Al<sub>4</sub>C<sub>3</sub>, which hydrolyses in the presence of moisture. Other complications arise when reinforcements are

SCs, which have electrical resistivities that can span orders of magnitude and are sensitive to impurity levels. In addition, impurities in semiconducting reinforcements may cause them to become n-type or p-type which can lead to photo-induced corrosion or even beneficial photoinduced cathodic protection. The presence of the reinforcements may also influence the formation of intermetallics and the generation of dislocations, which also affect corrosion behavior. These additional concerns make designing and utilizing MMCs a significant, but worthy, engineering challenge. Many of the extraordinary mechanical and physical properties of MMCs cannot be achieved with conventional metal alloys. Standardization of MMC constituents (e.g., purity levels in reinforcements) and the stringent control of processing temperatures and histories could help develop MMCs with more predictable corrosion behavior.

### Glossary

#### **Advanced (advanced technical, fine) ceramic**

A highly engineered, high-performance, predominantly nonmetallic, inorganic, ceramic material having specific functional attributes (*Note:* US – advanced ceramic;

Europe – advanced technical ceramic; Japan (English term) – fine ceramic; Germany – Hochleistungskeramik).

**Ceramic** An inorganic, nonmetallic material consolidated by the action of heat.

**Chemical porcelain** A ceramic material manufactured principally from clays, feldspars and quartz, and/or alumina, and generally of low iron content.

**Chemical stoneware** A ceramic material manufactured principally from clays, feldspars and quartz, and/or alumina, designed to retain dimensions during firing, and manufactured in large pieces.

**Chemical vapor deposition (CVD)** Method of producing a coating on a body (and more rarely a solid object on a mandrel) by reaction between gases at high temperature, for example,  $\text{SiCl}_4 + \text{CH}_4$ , producing  $\text{SiC}$ .

**Corrodant** Substance causing corrosion.

**Delayed failure** The sudden failure of a ceramic component without detectable creep as a result of subcritical crack growth under stress.

**Flexural strength** The fracture stress of a defined beam test-piece loaded in flexure and computed as the nominal tensile surface stress; usually applied to ceramic and other brittle materials.

**Glass-ceramic** A material fabricated as a glass which is then subjected to a controlled crystallization (devitrification) process to give a fine-grained microstructure with desired properties.

**Hardmetal** A metal/ceramic composite material comprising typically a hard ceramic phase with a metallic binder phase. Examples: WC/Co, WC/Ni, TiC/Fe.

**High-alumina ceramic** An advanced ceramic material comprising principally a compound of aluminium and oxygen with or without other minor components to aid densification or control properties.

**Hydration** The formation of a hydroxide material, especially at the corrosion interface of a material, especially a ceramic.

**Mullite** A ceramic phase comprising a compound of alumina and silica.

**Nonoxide ceramic** An advanced ceramic material comprising principally borides, carbides, nitrides, or silicides, for example, silicon nitride, molybdenum disilicide.

**Reaction bonding** A process for ceramic manufacture in which a ceramic bond between grains is produced *in situ* by chemical reaction between relevant species,

for example, between silicon and nitrogen to produce silicon nitride.

**Subcritical crack growth** The process of crack extension over time without complete failure.

**TZP (tetragonal zirconia polycrystals)** A zirconia ceramic, typically, but not exclusively, partially stabilized with yttria (hence Y-TZP) and with submicrometer grain size to retain principally the tetragonal phase of zirconia, resulting in high strength.

**Zirconia ceramic** An advanced technical ceramic material comprising principally a compound of zirconium and oxygen with or without other minor components to provide phase stabilization, to aid densification or to control properties.

## Abbreviations

**CBN** Cubic boron nitride

**CVD** Chemical vapor deposition

**HBN** Hexagonal boron nitride

**PTFE** Polytetrafluoroethylene

**TZP** Tetragonal zirconia polycrystal

## 3.25.1 Ceramic Materials as Engineering Products

### 3.25.1.1 Ceramic Materials and Applications

For many years, ceramic materials have formed a vital part of the palette of materials available for engineers, but with the principal disadvantage that they are brittle and may not be available in particularly large sizes. In former times, the choice was limited to porcelain-like products, which could be made for items such as pestles, mortars, mills, and chemical plant tower packings. Such materials generally have good resistance to being attacked by aqueous solutions up to 100 °C. Their principal advantage is that they produce no corrosion scale layers and no obvious metallic contamination of the process for which they are used. However, such materials are not particularly strong and/or wear resistant. Over the last half-century, the development of a wider range of harder and stronger materials for general engineering applications has greatly widened the field of applications from a corrosion

perspective. Such newer products have improved the performance of a wide range of existing devices compared with the use of metallic components, and have enabled new applications and processes to be developed, upon which the entire world now relies.

### **3.25.1.2 Mechanical and Thermal Limitations**

The main disadvantage of ceramic materials is that they are, in engineers' terms, brittle. They generally show linear elastic behavior to fracture, which occurs at strains of less than 0.5%, usually less than 0.1%. They therefore have to be treated with care from the design and application point of view. There must be an avoidance of stress concentrations that initiate fracture, which means that the designer should change his/her mindset, throw away his/her metallic designs with all their in-built assumptions, and start from scratch with chunky designs, which minimize stresses and thus maximize reliability. Failures in trials often result from poor or inappropriate design and a failure to understand stress concentrations and thermal gradients, as much as from attempting to use an inappropriate material.

A further consequence of brittleness is a limitation to thermal stress and thermal shock resistance. Steep temperature gradients or sudden changes of surface temperature, particularly downshock, can result in internal stresses, which are not relaxed by plastic deformation processes, but which can cause rapid failure. The larger the item, the more it is prone to thermal stress failure. Care is needed in the choice of material to withstand thermal shock. In general, for dense, fine-grained materials, thermal stress is reduced and thermal shock resistance is improved with reductions in thermal expansion coefficient and elastic modulus, and with increases in thermal conductivity and strength. Materials that have larger grain sizes, perhaps some open porosity, and lower elastic modulus, such as many refractory products, may show better thermal shock resistance than do finer-grained, denser, stronger materials, because the elastic energy developed is less, and damage takes the form of microcracking rather than macrocracking. Changing the material to maximize thermal shock resistance may have limitations in terms of resistance to corrosive attack. Therefore, care in material selection has to be taken. Unless parts are of thin sections, where concerns about thermal stress are less, it may be better to design the whole function to restrict thermal

stressing occurring while retaining the corrosion resistance of the material of choice.

## **3.25.2 Microstructure and Corrosion Processes**

### **3.25.2.1 Role of Microstructure**

Ceramic materials are typically made by a powder route, with a high temperature consolidation process to form the final microstructure. This process may be *via* solid state diffusion or sintering, or *via* a liquid phase mechanism, or *via* a combination of the two. In many cases, it leaves a continuous second phase, often of a glassy or partially crystallized nature, running between the grains. This is a key aspect of ceramic microstructures that needs to be considered from the point of view of corrosion. It means that not only the base crystalline phase or phases, but also the secondary, often unspecified, continuous phase, has to be resistant to corrosion in the medium under consideration.

An example of this is the series of materials known as high-alumina ceramics. By itself, high-purity alumina powder requires a high sintering temperature, and particularly expensive raw materials. Usually, a small amount of MgO is added to control grain growth during sintering, and this tends to segregate to grain boundaries along with any residual impurities such as sodium. For control of electrical properties such as dielectric loss, small additions of silica are made to create a glassy phase. Reductions in firing temperature can be achieved by adding additional components such as CaO. Although the alumina grains themselves are corrosion resistant, the resulting continuous grain boundary phase may not be, especially in acid media where the material can be penetrated through this phase without necessarily any change in dimensions or appearance. Such penetration can be disastrous for strength, wear, and erosion resistance, as well as for any process containment. Thus, although there may be claims that might seem to indicate that high-alumina ceramics have generically good corrosion resistance, which would be borne out for high-purity materials, it is not generally the case. Materials have to be chosen for their individual fitness for purpose, balanced against the ability to make the size and shape required. Often, it is necessary to undertake a test under the specific conditions of anticipated use to prove that they have the required corrosion resistance.

The majority of ceramic materials contain some residual porosity as a result of the process route

used in their fabrication. For engineering purposes, selected materials should be specified as being 'impervious,' in which case the pores are individual, and mostly not connected to each other. Liquids cannot penetrate the material except by dissolving a continuous phase. In some cases, this porosity is 'open,' that is, it is accessible from the exterior of the body, and there is a large accessible internal surface area that is subject to corrosive attack. With some materials, notably with chemical porcelains and stonewares, the integrity of the item may rely on an intact, impervious skin, which, if broken, permits corrodants to access the more-porous bulk.

Further details concerning individual material types are found in later sections.

### 3.25.2.2 Corrosion Processes

While corrosion of metallic alloys involves the dissolution or oxidation/hydroxylation of metal atoms at the surface, usually with electrolytic drivers, oxide ceramics are already oxides, and are usually quite stable against further hydration except under hydrothermal conditions (temperatures of 300–500 °C and pressures of 10s or 100s of atmospheres). They may possess a surface monolayer of hydroxide, but typically, this is stable. Removal of material from such a surface by aqueous environments requires chemical dissolution of the ceramic structure itself. In materials such as high-purity, single-phase alumina or silicon carbide, this is difficult; hence the corrosion resistance.

Some single-phase products have only moderate corrosion resistance in acidic or alkaline environments, notably those that are based primarily on alkaline or acidic oxides. Thus, magnesium and calcium silicates and some aluminosilicates tend not to be acid resistant, while silica and highly siliceous glasses tend to be relatively resistant to acids, but are attacked by strongly alkaline environments.

In structures with corrosion-resistant primary grains and secondary phases such as glasses, attack may be much more rapid, especially if the glassy network is highly disrupted by locally high levels of alkaline and alkaline earth ions. Acidic environments can much more readily attack this glassy phase. It is quickly leached of its alkaline ions, leaving a porous siliceous gel acting as a diffusion medium for the corroding species. Another example is of the free silicon phase in some versions of silicon carbide ceramics. The result is that the material can be penetrated down the grain boundaries without the

generation of any surface layers and without loss of dimensions.

In nonoxide ceramics, which are free from oxide phases, the first step to dissolution is oxidation or hydration. In silicon carbide and silicon nitride, the surface comprises a protective layer of silica. To progressively remove material, not only does this layer have to be removed, requiring a strongly alkaline condition, but also the underlying material then has to be oxidized. Only certain corrodant conditions will achieve this, hence the corrosion resistance of such materials. In some cases, the material oxidizes or hydrates readily. An example is the soft, crystallographically hexagonal form (HBN) of boron nitride. The oxide product is boric oxide, which readily reacts with water. Once hydration occurs at a significant rate, dissolution is continuous, and there is no protective skin.

The majority of commonly available ceramics for structural purposes are not electrically conducting to any significant extent at temperatures up to 500 °C. Consequently, they do not suffer from electrolytic effects, and hence from corrosion processes that involve this type of process. Only in materials that are electronically or ionically conducting, one might see such effects. With a few exceptions (e.g., siliconized silicon carbide), such materials are generally not employed for corrosion-resisting functions. However, an interesting example of a study of electrolytic corrosion of titanium-based ceramics and ceramic composites (TiN, Ti(C,N), TiB<sub>2</sub>) in seawater has been made by Lavrenko *et al.*<sup>1</sup> They showed that the rate of corrosion was three or four orders of magnitude less than in the majority of metallic materials, and that the process was dominated by the formation of a TiO<sub>2</sub>-based layer, which was analyzed in detail.

### 3.25.2.3 Subcritical Crack Growth

It is well established that the strength of many types of ceramic materials is determined by small defects or 'flaws,' which can be located in the bulk or at the surface. The combination of the largest flaw and the most highly stressed location determines the short-term strength. If such flaws are accessible to the external environment, the strength may be controlled by that environment through its effect on the process of breaking atomic bonds at the tips of stressed flaws. The net effect of this 'subcritical crack growth' is that both the short-term strength and the lifetime under steady applied stress are reduced.

The key element in this process is the presence of water, or more exactly,  $\text{OH}^-$  ions at the crack tip. The effect is accelerated by high temperature, and is influenced by pH. Glasses are the most susceptible of materials, followed by oxide-based ceramics and nonoxide-based materials with oxidic continuous secondary phases. Nonoxides that are inert to water, such as some silicon carbides, show very little effect.

The susceptibility of materials to this effect can be determined either by conducting strength tests at a wide range of stressing rates (four or more orders of magnitude), or by undertaking crack growth experiments on long-crack fracture toughness test-pieces. The information derived may be of importance for applications in which the actual bulk corrosion rates are very low or negligible, but the material is highly stressed.

#### 3.25.2.4 Corrosion/Erosion

There is a strong synergistic effect of corrosion and wear or erosion. There are two principal processes:

- The enhanced reaction between the medium and the ceramic surface, brought about by raised local temperature and the simultaneous removal of the reaction product;
- The undercutting of surface grains by the corrodant penetrating grain boundaries, followed by the mechanical removal of grains.

The first mechanism occurs in dense materials in which the grain boundaries are not preferentially penetrated. An example is in silicon carbide or silicon nitride subjected to sliding wear against a similar counterface. In these cases, the wear process enhances hydration of the surface to silica, which is progressively removed through the sliding process. The rate may be low, but is the principal damage mechanism in sliding seal wear. The second mechanism is when the rate-determining factors are chemical penetration and grain loosening.

### 3.25.3 Testing Procedures and Standards

#### 3.25.3.1 Standards

Testing standards for aqueous-based corrosion performance are generally flexible in corrodant conditions and duration to allow for a very wide range of potential applications in which particular conditions

may arise. For example, ASTM C 650 for ceramic tile permits any corroding substance of application relevance, advises against the use of HF because of its obvious rapid attack on any silicate-based material, and suggests that a general indication of respectively acid or alkali resistance can be obtained by the use of 10% HCl or 10% KOH at room temperature for 24 h. This standard uses visual color and texture change as the main indicator of attack, preferred to the measurement of change of gloss or mass change. A similar test is available as EN ISO 10545-13 (superseeding EN 106 and EN 122) for both unglazed and glazed tiles, using visual assessment of changes in surface appearance, and for glazed tiles, a 'pencil' test for the roughening of a glazed surface. The test duration is rather more extended than in ASTM C 650.

A test with a specific purpose in mind is described in BS4789 for alumina and beryllia ceramics for vacuum envelopes. It involves boiling in concentrated nitric acid (sp. gr. 1.42), followed by washing in water, then dilute ammonia, and again in water. The test-pieces are then conditioned by heating to 1200 °C for 30 min before weighing and calculation of mass loss. There is also a requirement to inspect for local cracking and spalling. The original intention behind this test was to determine whether the ceramic materials could withstand the removal of metallizing by acid digestion, followed by reprocessing at high temperature, and still maintain integrity and vacuum-tightness. This test originated from work reported by Binns.<sup>2</sup> Experience has shown that it is indeed very effective in identifying those materials that can be rapidly penetrated by acids.

A more general procedure is listed in CEN EN 12923-1. This provides guidance on the use of various criteria in deciding the extent of corrosive attack under any aqueous-based conditions. It provides options for characterization microstructurally, by mass change, dimension change, hardness change, flexural strength change, and by analysis of species dissolved into the reactant.

ISO 17092 provides methods for acid and alkali attack based on standardized HCl and NaOH solutions that are similar in principle to ASTM C 650, but intended for engineering type materials.

ISO 6474 (alumina) and ISO 13356 (zirconia) specifying ceramics for human body implantation such as in orthopedics require evidence that there is no change in strength after immersion in a simulated body fluid (saline, bovine serum, or the like) as one of the criteria for acceptability.

ASTM C 1368 and EN 843-3 provide methods for studying subcritical crack growth in an optional medium, which can include corrosive liquids. It is based on flexural strength testing at a series of rates over at least four orders of magnitude in loading or straining rate. The variation of mean strength with stressing or straining rate is used to compute the subcritical crack growth exponent  $n$ . This method is typically limited to tests of a few hours' duration, and therefore, if longer durations of exposure (and slower rates of attack) are relevant, the alternative method is dead-load 'delayed failure' testing, but this method has only been standardized so far in ASTM C 1576.

### 3.25.3.2 Procedures

#### 3.25.3.2.1 Equipment

In conducting corrosion tests in highly corroding media, it is necessary to consider carefully the containment vessels, and whether they themselves will be corroded to an extent that may affect the outcome of the test. Borosilicate glass vessels are usually perfectly adequate for acid tests at ambient pressure, but may have limited life under alkali tests. Test-pieces can be suspended in baskets or from wires, but should be separate from each other and should not rest on the bottom of the vessel to avoid erosion or damage, notably during boiling tests.

In the modern era, the safest way of undertaking aggressive corrosion tests is to use polytetrafluoroethylene (PTFE)-lined digestion bombs placed in an oven at the relevant temperature. Tests at temperatures of up to 200 °C can usually be undertaken without damaging the PTFE, giving pressures of up to 10 atm dictated by the certified maximum for the vessel. The advantage is the small volume of corrodant being handled, especially if it is subsequently being analyzed for dissolved species. The disadvantage is the limited volume of corrodant that can be employed, which might lead to exhaustion, and the fact that it is static within the vessel, which can lead to some areas of corrosion shielding.

It is sometimes necessary to understand the performance of materials in the presence of combined corrosion and erosion or abrasion. Such tests are certainly relevant to plant operation where fluids and possibly abrasive debris are being circulated, but are more difficult to set up in a meaningful way and to control in the laboratory. Cox and Morrell<sup>3</sup> describe a method of acidic and alkaline slurry erosion based on a spinning disc, applied to alumina

ceramics for chemical plant pipeline use. Wear of baffles intended to induce turbulence to avoid laminar flow films, coupled with changes in dimensions of the test discs led to some nonlinearity of conditions. Nevertheless, differences between different materials and corrodants were adequately demonstrated.

Standardized abrasive wear testing of hard materials is typically undertaken in rotating wheel experiments using loose abrasive, which becomes trapped between the wheel and the test-piece. Examples are ASTM B 611 (hard metals, steel wheel, brown alumina grit in water), ASTM G 65 (general applications, rubber edged wheel, sand, dry), and the light wear ball-cratering test (CEN EN 1071-6 intended for ceramic coatings). With suitable precautions, these tests can also be used with acidic or alkaline environments, which can be fed along with the abrasive. This approach can be used to study the synergistic effect of simultaneous corrosion and abrasion.

#### 3.25.3.2.2 Assessment techniques

##### *Mass change*

Measurements of mass change following corrosion can be misleading with ceramics. This type of test works well for materials that are uniformly dissolved, but if there is grain boundary penetration, corrosion products can be variably trapped in the developed porosity. Washing and drying, even refiring to high temperature, does not necessarily remove them all. It is even possible to obtain a mass gain despite clear penetration, which is clearly misleading if candidate materials are ranked solely using mass change. It is recommended that mass change tests are always used in conjunction with a test that is not influenced by residual corrosion products.

##### *Change of cross-section*

This test has the same limitations and problems as with testing metallic materials. It may not provide a particularly relevant result on ceramics under aqueous corrosion conditions, because generally size changes are very small if the primary phases are not attacked, and of course, penetration is not characterized. In some cases, the method may have value, where there is clear loss in section, for example, when corrosion is combined with erosion or wear.

The most reliable method is usually the preparation of a cross-section and its dimensioning using a measuring microscope.

**Dye penetration**

This is an extremely useful test. Test-pieces are simply immersed for an hour or two in a suitable dye solution after corrosion and washing. After washing in solvent, the greater retention of dye compared with uncorroded material is an initial indicator of some penetration, which can be confirmed by sectioning or fracturing the test item. If the corrosion tests have been conducted on flexural strength test bars (see the following section), the depth of penetration is easily seen after fracture.

**Flexural strength**

For smaller-sized parts, which may suffer a risk of fracture in the intended application, knowledge of any reduction in strength as a result of corrosion can be important. Such tests are normally performed on standardized flexural strength test-pieces, typically  $>45 \text{ mm} \times 4 \text{ mm} \times 3 \text{ mm}$  tested in four-point flexure (ASTM C 1161, CEN EN 843-1, ISO 14704) for advanced technical ceramics. It is recommended that at least 10 test-pieces are used for any one corrosive condition, as well as for the uncorroded reference state, in order to allow for the typical spread of strengths typically obtained with brittle materials.

**Change of surface texture**

The roughening or pitting of a ceramic surface can occur in corrosion, and this can be characterized using conventional roughness measurement techniques. Caution is needed with the texture characterization of ceramic surfaces in general, and the guidance given in EN 623-4 is intended to encourage good and relevant practice.

**Hardness**

Surfaces that suffer penetration lose apparent hardness. They may even become soft enough to be scratched or chipped using a knife, while micro- or macrohardness tests can be used to quantify such an effect (see EN 843-4, ISO 14706). The method is appropriate for small penetration depths, up to say  $20\text{--}50 \mu\text{m}$ , which might not reveal themselves as changes in strength, but not for larger depths where the test may become meaningless.

**Chemical changes to the corrodant**

Chemical analysis of the corrodant after the test can offer an insight into which species in a multicomponent material are being preferentially removed. Very sensitive techniques are available.

**General comments**

Care should be taken to ensure that any loose or precipitated material is fully accounted for. Material can be dissolved and reprecipitated elsewhere, including the vessel walls and sample suspension system. An example of what can be achieved and some of the pitfalls are given by Öhman *et al.*,<sup>4</sup> who studied the leaching of high-purity alumina by sodium bicarbonate buffered water. They determined that in this case, gravimetric methods of determining material loss give significantly greater values than determined by using a fluoroscopic method of analyzing the corrodant solution. An analysis of solution equilibrium calculations showed that precipitation was unlikely, but far more likely was the development of a surface skin by a hydration/precipitation mechanism, which when dried out for test-piece weighing gave a friable surface, which was readily lost.

**3.25.3.3 Testing Standards**

Following are the standards providing testing methods relevant to various varieties of ceramics:

EN 12923-1:2006 Advanced technical ceramics – Monolithic ceramics – Part 1: General practice for undertaking corrosion tests (Generic standard for technical and engineering materials providing procedures for determining attack, appropriate for any reagent.)

ISO 17092:2005 Fine ceramics (advanced ceramics, advanced technical ceramics) – Determination of corrosion resistance of monolithic ceramics in acid and alkaline solution. (Testing in 6 N  $\text{H}_2\text{SO}_4$  and NaOH boiling solutions for 24 h with attack criteria being mass loss, dimension changes, and loss of mechanical strength.)

EN ISO 10545-13:1997 Ceramic tiles – Part 13: Determination of chemical resistance. (A variety of test solutions permitted, including ammonium chloride (representing household cleaning products), sodium hypochlorite (swimming pools), HCl, citric acid, KOH, and lactic acid (foodstuffs), used for 24 h on glazed surfaces. Criteria based on visual inspection, reflectivity, and ‘pencil’ test.)

EN 993-16:1995 Methods of test for dense shaped refractory products. Determination of resistance to sulfuric acid

ISO 28706-4 Vitreous and porcelain enamels. Determination of resistance to chemical corrosion. Part 1: Determination of resistance to chemical corrosion by acids at room temperature.

Part 2: Determination of resistance to chemical corrosion by boiling acids, neutral liquids, and/or their vapors.

Part 3: Determination of resistance to chemical corrosion by alkaline liquids, using a hexagonal vessel

Part 4: Determination of resistance to chemical corrosion by alkaline liquids, using a cylindrical vessel

### 3.25.4 Performance of Specific Material Types

#### 3.25.4.1 Oxide-Based Materials

##### 3.25.4.1.1 Porcelains and aluminosilicates

The longevity of many silica-based materials, including earthenware, porcelains, and even some glasses, in wet environments is eminently demonstrated by archaeological evidence. Most clay-based materials comprise crystalline phases such as quartz, cristobalite, and mullite embedded in a glassy matrix produced by melting mineral phases containing alkalis and alkaline earth species. The solubility of such glasses in water is limited, and while the attack does slowly occur by a leaching/hydration process, it does not restrict their use in many applications. In fact, they will also withstand some aggressive, aqueous environments, such as strong acid and alkaline solutions.

For applications in the kitchen and the laboratory, so-called ‘chemical porcelains’ with very low or zero open porosity without glazes have been in use for many years, particularly in the pharmaceutical industry, and are not radically different in structure from materials used for electrical insulators. They have been employed in a range of applications, the most commonly known one being pestles and mortars, up to some moderate-sized items for use as one-piece corrosion and abrasion-resistant linings. However, one of the limitations of such materials is their manufacture in large pieces. The shrinkage obtained on firing makes shape and dimension control difficult. One long-standing route around this problem is to restrict the shrinkage by adding prefired refractory particulates to the clay mix. However, this allows porosity to be developed, and often a product will only remain impervious if the surface skin, which effectively seals the bulk microstructure, remains intact. Such materials, often called ‘chemical stoneware,’ can be made in the large pieces required for chemical tower packing, and still remain the preferred

option for large-sale use. Similar materials are used for corrosion-resistant hygienic tiling of surfaces.

In addition, similar materials are available in brick form for building structural chemical plant linings. Varieties are available with microstructures appropriate for acid or alkali resistance. These would be grouted with appropriate acid- or alkaline-resistant cements, which although not as corrosion resistant as the bricks, survive sufficiently for the vessel to survive and prevent corrosion of external steelwork. The scientific literature on such materials is very limited, but Charlebois<sup>5</sup> has described a number of such applications, including sulfite digesters in the paper industry, sodium chlorate tanks, and tanks for HCl leaching of TiO<sub>2</sub> ore.

Bennett<sup>6</sup> reports on sulfuric acid testing of four aluminosilicate brick materials made from different sources of red shale or fireclay, but all show rather higher rates of attack than SiC, silica, carbon, or alumina, minimum rates being obtained with carbon and alumina.

Marcus and Ahrens<sup>7</sup> show that highly siliceous materials (fused silica glass, sintered mullite, and sintered clay/zircon) have rather lower corrosion rates in concentrated phosphoric acid at 204 °C than many nonsiliceous oxides (alumina, beryllia, spinel), cordierite (2MgO·2Al<sub>2</sub>O<sub>3</sub>·5SiO<sub>2</sub>) showing intermediate behavior.

##### 3.25.4.1.2 Alumina

The ceramic family most commonly employed for engineering components is that based on aluminum oxide (alumina, Al<sub>2</sub>O<sub>3</sub>), being generally stronger, harder, and more abrasion resistant than porcelains. There is a huge spectrum of types of alumina ceramic depending on their intended engineering function. Containing more than 80% by mass of Al<sub>2</sub>O<sub>3</sub>, but more typically in excess of 95%, they usually have additional components added to control the sintering process, to reduce the sintering temperature, or to modify the final properties. It is probably true to say that no two alumina ceramics from different sources are the same in all respects, but some generalizations may be helpful (more details can be found in Morrell<sup>8</sup>):

1. High-purity alumina without additions does not sinter well and tends to suffer from exaggerated grain growth. Such materials tend to be used only for crucibles.
2. High-purity alumina with small controlled amounts of MgO or Y<sub>2</sub>O<sub>3</sub> when in ultrafine powder form can be sintered to full density with control of grain

size. Such products include biomedical implants (fine-grained) or translucent lamp envelopes (medium-coarse grained).

3. Aluminas of lesser purity (sometimes called 'debased' alumina) used for lower value-added products, for example, in electronics, usually have deliberate additions of MgO, SiO<sub>2</sub>, and CaO. This produces a distinct secondary glassy phase, which can act as a sink for impurities such as alkalis, and thereby control dielectric properties, especially loss tangent.
4. Alumina ceramics for general engineering may be similar to those for electrical purposes in terms of compositions; indeed often, a given product is treated as multifunctional. Others, such as those sintered using MnO and TiO<sub>2</sub>, which produce a low-temperature eutectic liquid during firing, tend to have applications restricted to mechanical ones. More generally, if strength and wear/erosion resistance is an important feature, products tend to be of finer grain size than used for many electrical applications.
5. While the majority of aluminas are highly resistant to corrosion in high pH or neutral solutions, only a few products are designed for resistance to aqueous corrosion at low pH. This requires control of the nature of the secondary phase composition.

There is an extensive literature on corrosion resistance. Thermodynamically, Al<sub>2</sub>O<sub>3</sub> is not stable in water, but is attacked only very slowly. Öhman *et al.*<sup>4</sup> evaluated the rate of attack of simulated groundwater on a high-purity alumina hot-pressed material substantially free from secondary phases. The buffered sodium bicarbonate solution used gave pH 8.5. In tests of up to 90 days' duration and at temperatures in the range 40 °C–100 °C, depths of corrosion determined by mass loss and fluoroscopic analysis for aluminum in the corrodant solution were of the order of only a few nanometers. As mentioned earlier, the factor of 5 discrepancy between the two analysis methods was ascribed to the development of a hydrated surface skin, which was readily lost when dried. A similar very thin deposited layer was found by Real *et al.*<sup>9</sup> in tests on a similar sintered material boiled for 2 weeks in 5% salt solution. This treatment did not significantly affect the strength or the apparent hardness of the material.

One of the first systematic studies of corrosion resistance was made on a fairly high-purity crucible material, conducted by Jaeger and Kraseman.<sup>10</sup> Attack by various acidic and alkaline solutions at 95 °C for 3 days was very significant for HF and

**Table 1** Corrosion resistance of alumina ceramics<sup>11</sup>

Body no.	Composition (wt%)				Mass loss, 50% HNO <sub>3</sub> , RT, 18 h (mg cm <sup>-2</sup> )
	Al <sub>2</sub> O <sub>3</sub>	CaO	MgO	SiO <sub>2</sub>	
1	94.1	1.8	0.7	3.4	7.0
2	94.7	1.7	1.2	2.4	5.0
3	95.2	1.0	0.7	3.1	3.5

HF/H<sub>2</sub>SO<sub>4</sub> and for strong (1:2) NaOH solution. For many other acids, attack was slow.

Richards<sup>11</sup> reported the corrosion resistance of experimental 'debased' alumina ceramics in HNO<sub>3</sub> as a function of secondary phase composition. From the data provided (Table 1), it can be seen that the mass loss rate can vary by more than a factor of 100, depending on the ratio of MgO:CaO:SiO<sub>2</sub>. It can be concluded that the best resistance is achieved when the ratio of alkaline earths to silica in the secondary phase is small, and when the amount of CaO is minimized. Commercial products are available that are free from CaO for maximized resistance to acidic corrosion, but have a disadvantage that they tend to have lower toughness because of an increased thermal expansion mismatch between the alumina grains and the secondary phase.

These findings are supported by the work undertaken at NPL during the 1970s.<sup>12, 13</sup> A variety of alumina ceramics of between 95% and 99.8% were tested in H<sub>2</sub>SO<sub>4</sub> (10%, v/v, boiling, 72 h), HCl (20%, w/v, boiling, 72 h), HNO<sub>3</sub> (35%, w/v, boiling, 72 h), HF (40% solution, 20 °C, 72 h), and KOH (10%, w/v, boiling, 72 h). The criteria used were weight loss and spalling tendency on reheating to 1000 °C (Figure 1), dye penetration (Figure 2), strength loss, and hardness loss. The principal results are shown in Table 2.

A summary of some of the conclusions is as follows:

1. A translucent high-purity alumina was found to be resistant to all acids with no detectable weight loss, dye penetration, or tendency to spall.
2. A number of refractory or electrical aluminas (up to 99.7% Al<sub>2</sub>O<sub>3</sub>) were badly attacked in all acids, and some pitted badly or disintegrated when reheated indicating the presence of trapped corrosion products. There were significant losses in strength and hardness, indicating the development

of a porous layer, but without any significant loss in dimensions.

3. A 95% material claimed to be acid resistant was found to be so compared with most others, except in HF, which attacks the siliceous phase. In this

material, most of the CaO is replaced by MgO, and the SiO<sub>2</sub> content raised to provide a relatively corrosion-resistant intergranular glassy phase.

4. Alumina itself is slowly dissolved by strong alkalis, but there is much less preferential penetration

through any intergranular phase, resulting in a progressive removal of the surface rather than the penetration seen with acids. Strength as measured in a flexural test on small test-pieces, which preferentially stresses the corroded surface, tends to be better maintained than in acids.

Later work at NPL<sup>3</sup> evaluated the effects of combined corrosion and erosion in acids and alkalis on a small range of alumina ceramics. Three alumina ceramics were employed, two fine-grained, of nominal 99.5%, and one coarse-grained, of nominal 97.5% alumina. Tests were made on discs spinning in a heated corrosive liquid, with and without SiC as a hard particle erodant, as well as on test-bars suspended in the liquid. All the three materials were significantly penetrated by acidic solutions, HCl being the most aggressive. The 97.5% alumina was attacked much faster than were the 99.5% materials, but these showed significant differences in behavior. **Figure 3** shows the change in flexural strength measured at room temperature for different corrodant types. Immersion in KOH solution produced the least effect. There were very minor changes in both mass and strength as a result of immersion in water.

The addition of 5% (v/v) SiC grit to acidic corrodants in these tests resulted in an acceleration in the rate of mass loss by a factor of between 2 and 4

compared with tests in liquid only. This is explained by the fact that the removal of the secondary phase renders the remaining material rather weaker and more readily eroded. By comparison, the erosion rate in KOH solution was only slightly faster than that in water at the same temperature, indicating that the microstructure is not weakened in the same way.

Engell and Jakobsen<sup>15</sup> have reviewed corrosion mechanisms in alumina ceramics used for liquid pump parts, including brown-colored versions incorporating MnO and TiO<sub>2</sub> as low-temperature liquid phase formers. Tests were run for up to 5000 h at 90 °C at pH 5.5, 9, and 12 buffered by NaOH. **Figure 4** summarizes some of their results. The rates of attack increase with increasing pH over this range, but there are significant variations between the materials.

Genthe and Hausner<sup>16</sup> studied single-crystal sapphire and ruby, and high-purity hot-pressed aluminas with and without MgO and Cr<sub>2</sub>O<sub>3</sub> dopants. The dissolution rates in HCl and H<sub>2</sub>SO<sub>4</sub> (180 °C, 168 h) were minimal for single-crystal materials, but greater for polycrystalline ones, which was attributed to the preferential removal of the grain boundary phase. In H<sub>2</sub>SO<sub>4</sub>/H<sub>3</sub>PO<sub>4</sub> mixtures, attack rates were significantly higher owing to the dissolution of alumina itself, although increasing amounts of Cr<sub>2</sub>O<sub>3</sub> tended to suppress this process.

**Figure 3** Loss in strength of test-bars immersed in flowing liquid for 23 h in various corrodants (data from Ref. 3).

**Figure 4** Corrosion test results from Ref. 15 at 90 °C on brown and white alumina ceramics from different manufacturers. (Note: not all combinations were tested.)

Mikeska *et al.*<sup>17</sup> report that all alumina ceramics, including those of nominally very high purity, other than single-crystal sapphire are very significantly attacked by HF at 90 °C as a result of grain boundary phases, the effect being worst with high levels of silica in the secondary phase. Fang *et al.*<sup>18</sup> show that an 85% alumina is rapidly penetrated by a 1% HF + 5% HCl solution at room temperature, to leave a porous layer that was readily eroded in a subsequent wet sand erosion test.

Tests on 94% and 99% aluminas in concentrated (96%) phosphoric acid have been reported by Marcus and Ahrens.<sup>7</sup> At room temperature, the dissolution rate was minimal over a period of a month, but at 204 °C, the higher-purity material was attacked faster with a dissolution rate equivalent to 450 mm year<sup>-1</sup>, compared with 35 mm year<sup>-1</sup> for the 94% material. This is likely to be a result of a slower reaction with the continuous glassy phase than with alumina itself.

Sato *et al.*<sup>19</sup> tested two aluminas at 150–200 °C in 0.1 M to 25 M NaOH. A 93% alumina material was attacked several times faster than was a 99.5% alumina, primarily by dissolution of the secondary phase. Small test-pieces (3 × 4 × 20 mm) were essentially consumed by the 25 M solution within a day at 200 °C and within 5 days at 160 °C.

This wide range of performance implies that although alumina ceramics generally show good resistance to weak and neutral solutions, great care must be taken to select the most appropriate product if aggressively acidic service conditions are intended.

Materials not designed for acid resistance may be penetrated much faster than might be expected.

Dailly *et al.*<sup>20</sup> evaluated the stress-corrosion behavior of several types of electrical substrate alumina ceramic in air and in Ringer's solution (saline, appropriate for biomedical environments), using the double torsion plate method. In this method, the test-piece is rapidly loaded, and then the machine cross-head is stopped and the stress relaxation monitored as the crack progresses along the length of the plate. The crack velocity was determined from the relaxation rate. In all the cases, the crack velocity exponent ( $n$  in the relationship  $v = AK_I^n$  where  $v$  is the crack velocity,  $K_I$  is the stress intensity factor, and  $A$  is a constant) was in the range 17–30, indicating the clear existence of subcritical crack growth. This value was lower in saline than in moist air, that is, the material becomes more susceptible to crack growth. The results given do not provide a clear indication of what features of the composition, especially the relative proportions of the secondary components, control the behavior, but the authors suggest that the presence of MgO is disadvantageous. Byrne *et al.*<sup>21</sup> used the same technique on a variety of materials and found significant differences in crack growth in strong acids and alkalis. Barinov *et al.*<sup>22</sup> report similar large changes in  $n$  with different pH values for one alumina, but not another, using the method of flexural strength testing over a very wide range of testing rates.

Circumstantial evidence from *in vitro* and *in vivo* failures of highly loaded alumina femoral

components suggests that high-purity materials are not immune to the phenomenon, although Ferber and Brown<sup>23</sup> have found that the values of  $n$  are higher.

### 3.25.4.1.3 Zirconia

#### Material types

Zirconia in its pure form undergoes two solid-state phase transformations on cooling from the melt (cubic–tetragonal–monoclinic), making the production of useful ceramic materials impossible. Structural stabilization is required. To stabilize the cubic form, MgO, CaO, or Y<sub>2</sub>O<sub>3</sub> can be used in sufficient quantity; such products are known as *stabilized zirconia*. Such materials find uses as crucibles and oxygen sensors, but are not particularly strong or tough.

Developments in the 1970s were made with partially stabilized materials that enabled much stronger tougher products to be made. With MgO additions, a ceramic shape sintered in the cubic phase field is subjected to a programmed cooling schedule in which a fine-scale tetragonal phase precipitate is developed inside the large cubic grains (~30 µm). The destructive martensitic-like conversion of the tetragonal phase to the monoclinic phase with significantly lower density is avoided by constraint of the cubic phase and by retaining a small precipitate size. Such products are known as *transformation toughened partially stabilized zirconia*, but often just ‘partially stabilized zirconia.’ Mixed stabilizers are sometimes used instead of just MgO.

An alternative approach is with yttria additions, most commonly with 3 mol%. In this case, a very fine powder (<100 nm) is prepared at which size scale tetragonal zirconia is stable to below room temperature. This is sintered to a dense ceramic at a relatively low temperature (~1450 °C) in order to avoid excessive grain growth. Such materials typically have a grain size of ~0.5 µm, which is mostly the tetragonal phase, although the surface layer may contain some monoclinic phase. Such products are known as *tetragonal zirconia polycrystals* or more commonly as ‘TZP.’ When the stabilizer is yttria (‘Y-TZP’), this product has a high strength, and a wide range of applications, including biomedical devices such as hip joints, but has a limited performance at raised temperature because of an increased risk of progressive transformation from the surface. To circumvent this problem, alternative or mixed stabilizers have been proposed.<sup>24</sup> Research has been conducted on the use of other lanthanides, such as scandia, but such materials are

primarily intended for oxygen ion conduction and are not generally commercially available.

The principle of transformation suppression in tetragonal ZrO<sub>2</sub> is also used to improve the strength of other ceramic materials, notably alumina.

#### Stabilized zirconia

Compared with TZP materials (see the later sections), cubic stabilized zirconia (CSZ) has been considered to be more stable to hydrothermal degradation. However, as shown by Guo and He,<sup>25</sup> an 8Y–ZrO<sub>2</sub> material typical of that used for oxygen ion sensors showed precipitation of the monoclinic phase after exposure to 0.026 atm. water vapor pressure at 250 °C, and some tendency to cracking, but with an increase in electrical conductivity.

Lay<sup>14</sup> reports significant rates of attack by boiling acid solutions on a CaO-stabilized material, especially H<sub>2</sub>SO<sub>4</sub>, but no attack by 80 °C solution of KOH. 6Y-CSZ and 8Y-CSZ are reported to be highly corrosion resistant, especially in neutral or alkaline solutions.<sup>26</sup>

#### Transformation toughened partially stabilized materials

Sato *et al.*<sup>27</sup> report that an MgO partially stabilized material does not undergo tetragonal-to-monoclinic transformation in 1 M HCl and 1 M sodium acetate–acetic acid pH 3 solution at up to 140 °C for up to 40 days, but some transformation and a loss of strength occurred when exposed to water at above 200 °C, Mg<sup>2+</sup> ions being detected in solution.

Fang *et al.*<sup>18</sup> report on corrosion testing of a UK origin material, partially stabilized with MgO and Y<sub>2</sub>O<sub>3</sub> and containing some SiO<sub>2</sub>, in an HF/HCl solution, simulating an oil pipeline cleaning solution. They noted that HF tended to attack the grain-boundary silica, while HCl attack tended to leach the yttrium and to destabilize and dissolve the zirconia grains. The process was thought to be such that the surface of the material was progressively removed with no significant influence on strength or erosion rate in a subsequent sand jet wet erosion test.

Mikeska *et al.*<sup>17</sup> report a corrosion penetration rate >100 mm year<sup>−1</sup> in HF at 90 °C.

#### Y-TZP, Ce-TZP, and Ce-Y-TZP

There is extensive literature on the problem of destabilization of Y-TZP in water or steam in the temperature range 150–400 °C, but there is no conclusive explanation. The most likely process is the diffusion of water into the ceramic, annihilating oxygen vacancies, releasing yttrium ions, and leaving the zirconia

grains with insufficient stabilization.<sup>28–31</sup> It has been suggested that the impurity content of the material affects this process, changing the level of stability,<sup>32–37</sup> but the exact mechanisms have not been conclusively determined. The net result is the expansile growth of groups of monoclinic zirconia grains on the surface, giving small raised regions that can be plucked out leaving a pit.<sup>31</sup> In the short term, such pits do not necessarily affect the strength of the material, but eventually macrocracking can occur.

Researchers usually characterize the process using X-ray diffraction and report the percentage of monoclinic phase at the surface. Using this approach, it has been shown that there is a nucleation delay for the process, of length determined by temperature, which has allowed prediction of rates at temperatures as low as 37 °C (orthopedic applications at human body temperature<sup>32</sup>). The process has also been found to be surface preparation dependent. Grinding the surface of this material caused some transformation to occur, often considered to be beneficial by creating high surface residual compressive stresses. Subsequent rates of transformation of such surfaces are different from those of as-fired surfaces, as illustrated in Figure 5. Other recent literature on this problem includes Refs. 29, 31, 39, and 40.

Bastide *et al.*<sup>24</sup> determined that the material containing 1 mol%  $Y_2O_3$  and 7 mol%  $CeO_2$  was stable at well below room temperature, was not quite as strong as 3 mol% Y-TZP, but possessed a good strength retention after exposure to steam at up to 300 °C up to 2000 h. Similar results have been reported.<sup>41,42</sup>

However, this product is not yet commercially available. Another route to improving the stability has been shown to be carbonitriding the surface in a  $ZrN + C$  bed at high temperature.<sup>43</sup> In contrast,  $Sc_2O_3$  stabilization has been found not to be effective in restricting hydrothermal transformation.<sup>44</sup>

In more severe chemical environments, Shojai and Mantyla<sup>45</sup> report that 3Y-TZP zirconia ceramic membranes lost weight in both acid and alkaline solutions at room temperature, but suggest that the material did not transform at a significantly enhanced rate compared with exposure to water.

For 3Y-TZP, Mikeska *et al.*<sup>17</sup> report a corrosion penetration rate  $>100$  mm year<sup>-1</sup> in HF at 90 °C.

Kritzer *et al.*<sup>46</sup> report on corrosion tests on a Ce-TZP, using HF and HBr at 24 MPa pressure at 500 °C. Some intergranular attack was noted, HF being less corrosive than HBr, but no weight loss or phase transformation was found.

Kalin *et al.*<sup>47</sup> describe Y-TZP ball on alumina disc wear test experiments, in which the rate of wear of the balls in the severe wear condition is pH-controlled. A low pH of 0.9 resulted in much lower friction and milder wear than did high pH values where the formation of distinct tribolayers led to grain fracture, rough surfaces, and high friction coefficients.

#### Composites with $ZrO_2$

Hisamori and Mimura<sup>48</sup> studied the role of Y- $ZrO_2$  additions to alumina, and found that with optimized amounts of the addition, there were some small improvements in average strength after exposure to deionized water at 200 °C and 1.59 MPa pressure,

**Figure 5** The transformation of Zyranox® Y-TZP material formed as flat tiles and as ceramic femoral heads as a function of time of exposure to simulated body fluid at 37 °C.<sup>38</sup>

although it was unclear why this should be the case. Microstructural analysis of the surface of the test-pieces showed that the presence of zirconia induced pitting with associated microcracks that might be associated with the transformation of surface-connected or near-surface zirconia grains. Herrmann *et al.*<sup>49</sup> demonstrate similar microstructural effects, and show that the corrosion rate under such conditions is higher than in pure alumina. Material made by Hirano and Inada<sup>50</sup> and by Nakanishi *et al.*<sup>51</sup> showed no change in monoclinic content after high temperature aging in water.

Thompson and Rawlings<sup>52</sup> identified structural changes in such a material when subjected to HCl attack. In medium- to long-term tests at room temperature, microcracking was associated with the leaching of yttria from the zirconia phase, and this eventually led to macrocracking. There was increased transformation of near-surface zirconia from the tetragonal to the monoclinic form. There was also a progressive loss in strength, compared with an initial drop and then a plateauing of the strength of the same alumina without reinforcement.

#### **3.25.4.1.4 Other oxide ceramics**

Mullite – Yoshio *et al.*<sup>53</sup> studied water attack at 300 °C and 8.6 MPa pressure on various synthetic mullite materials, and found that the mechanism of attack was dissolution of silica and the formation of a hydrated layer of boehmite (AlOOH). The composition of the mullite and the processing route adopted affect the results.

#### **3.25.4.1.5 Glasses and glass-ceramics**

##### **Glasses**

The majority of technical glasses are based on a network-forming oxide (such as silica, boric oxide, phosphoric oxide, etc.) modified with a range of other oxides. Of these, the silicate glasses are the more corrosion resistant, while the others tend to be readily attacked by water. In general, the greater the proportion of the network-modifying components in glasses, the less resistant they are to corrosion, because the remaining silicate network is more readily broken up, and the modifiers are more easily removed. Thus, many specialized glasses that are designed with specific control on expansion coefficients and glass transformation temperatures, for example, for sealing applications, tend to have a lesser ability to resist corrosion than does even window or bottle glass.

The ability of corrosive solutions to attack glasses thus depends primarily on glass composition and corrodant pH. Under near-neutral conditions, silicate glasses are very slowly hydrated at the surface, the surface being depleted of network modifying ions, such as Ca and Na by ion exchange. Silica itself is almost insoluble in water, except at elevated temperature and pressure. Good corrosion resistance is reported for high-silica, some borosilicate (e.g., Pyrex<sup>®</sup>), aluminosilicate, and high-lead compositions. Soda-lime, alkali-lead, lead borosilicate, and low-melting borosilicate sealing glasses have less good properties, while high-alkali, calcium aluminate, phosphate, and borate glasses have poor properties.

Under strongly acid conditions, network-modifying species are removed more readily, but the adequate stability of glass at room temperature is well demonstrated by the use of ordinary soda-lime glass containers for the long-term storage of mineral acids. Similarly, sodium borosilicate glasses are widely used for chemical processing in the laboratory and in chemical plant, but have the advantage of improved thermal shock resistance because of their lower expansion coefficients. High-silica glasses have the best acid resistance, while softer sealing glasses can be very rapidly attacked in mineral acids. An exception to this behavior is with HF, which attacks the silicate network, producing SiF<sub>4</sub>, so that many glass etchants and cleaning solutions contain HF as a primary component.<sup>54</sup> Glasses with a high CaO content are the most resistant to HF because of the formation of insoluble CaF<sub>2</sub>, which impedes the corrosion process.

Attack by strongly alkaline solutions is often more rapid than attack by mineral acids, because these actually dissolve the silicate network. Many dishwasher detergents are mildly alkaline, and over time can destroy the surface of glassware or glazed china-ware. The rate of corrosion is less composition dependent than with acid corrosion, aluminosilicate and special alkali-resistant compositions faring the best.

At higher temperatures, glasses become much less stable toward water-based corrodants. The surface layer can become like a sponge as the network modifiers are leached out. This has been exploited in the Vycor<sup>®</sup> process<sup>55</sup> for making high-silica glass; a sodium borosilicate glass is heat treated to cause two-phase separation to give interpenetrating silica-rich and silica-poor phases, the latter being readily removed by acids. A second heat treatment is used to densify the porous body.

### Glass-ceramics

Glass-ceramics are produced by the homogeneous nucleation and crystallization (sometimes known as 'devitrification') of special glass compositions.<sup>56</sup> This process allows the exploitation of glass-making to form ceramic and ceramic-glass shapes that have special characteristics not readily achievable by conventional ceramic sintering routes. There is a huge variety of compositional types for different purposes. Some examples include

Lithium aluminosilicates:	Low and near-zero expansion coefficients, for thermally shock-resistant cookware and cooker hobs (e.g., Pyroceram®), and for optical components such as telescope mirrors (e.g., Zerodur®). Photosensitive glasses, which after heat treatment can be selectively etched
Magnesium aluminosilicates:	Medium-to-low expansion coefficients, for electronic substrates, heat exchangers, high temperature uses
Lithium zinc silicates:	Medium-to-high expansion coefficients, for glass-metal sealing, lead throughs, etc.
Fluorine-silicates:	These devitrify to fluorine-based micas to give machinability, for example, Macor®, for prototype work, including dental ceramics.

The first two types listed have also been used for the fabrication of fiber-reinforced ceramic composites, using silicon carbide fibers and a hot-pressing route to manufacture.

In general, glass-ceramics are seldom optimized for aqueous-based corrosion resistance, and tend to be attacked faster than the parent glass. The baseline glass composition is devised to permit processing as a glass, while permitting control over the devitrification. Therefore, the microstructure generally comprises intended crystalline silicate phase assemblage plus a residual glassy phase. Like glasses, all will be rapidly attacked by HF, but in other common chemical species behavior will be very much composition dependent. Some examples of recent studies of corrosion behavior are given in Refs. 57–59.

Data on the corrosion resistance of Macor® machinable glass-ceramic are shown in Figure 6, taken from the manufacturer's brochure.<sup>60</sup> Compared with other oxide ceramics and glasses, the material appears to be significantly attacked by water. It is possible that the leaching of fluorine ions from the fluorine-based mica phase creates HF in solution. This

results in accelerating attack on the silicate phases if the HF is not removed by solvent replacement.

Some examples of stress-corrosion effects in water are given in Refs. 61–65.

### 3.25.4.2 Nonoxide-Based Materials

#### 3.25.4.2.1 Silicon carbides

##### Material types

Silicon carbides are among the most acid resistant of ceramics at up to 100 °C, but the behavior differs among the different types available for use in engineering and chemical applications:

1. Reaction-bonded silicon carbide is made by infiltration of silicon into a SiC/C mass, a process which forms bonding SiC and leaves a generally interpenetrating, continuous silicon phase filling the pore space. The principal advantage of this process route is the minimal size change that occurs.
2. Sintered silicon carbide is made by a high temperature sintering process, producing either a dense or a porous, nominally single-phase material. The material can be either  $\alpha$ -SiC (hexagonal structure) or  $\beta$ -SiC (cubic structure). There is usually some residual porosity.
3. Liquid-phase sintered silicon carbide is made by employing additions of typically yttria and alumina to form a liquid phase at the sintering temperature. This phase solidifies to a continuous second phase.

In addition, for special purposes, other microstructural modifications can be employed, including the addition of graphite flakes for the reduction of friction in sliding seals, and the deliberate generation of closed porosity to act as a liquid reservoir, also for seals.

##### Reaction-bonded silicon carbides

Tests at NPL have shown no significant mass loss or penetration of several types of reaction-bonded SiC for a range of acids. The most aggressive was boiling orthophosphoric acid, in which a mass loss of 0.3 mg cm<sup>-2</sup> was obtained in 30 min.<sup>12</sup> Similar results are cited by Marcus and Ahrens.<sup>7</sup> The only acid combination to produce much more rapid attack is HF/HNO<sub>3</sub>, which attacks the residual silicon phase by the dual process of oxidizing the surface to silica and the latter's immediate removal by HF. This combination can be used to remove completely any residual silicon, but it leaves a weakened, open-porous

**Figure 6** Corrosion test results on Macor® machinable glass-ceramic.<sup>60</sup>

material. In contrast, Fang *et al.*<sup>18</sup> show that an HF/HCl mixture at room temperature produces only a very slow attack rate. Strong alkalis, as exemplified by tests using 10% KOH at 80 °C for 168 h, also attack the material by direct rapid dissolution of the silicon phase, 30 mg cm<sup>-2</sup> mass loss being obtained.

At higher temperatures, hydrothermal conditions result in oxidation and the removal of the oxide. Thus in steam at 220 °C (20 bar) for 24 h, a mass loss of 1.9 mg cm<sup>-2</sup> was obtained. More recently, more extreme conditions have been evaluated on three materials with different free Si contents in water at 360 °C for 7 days.<sup>66</sup> The rate of mass loss increased with increasing Si content, the Si phase being leached away by water oxidation and by dissolution as silicic acid. The rate increased further when an initially alkaline solution (pH 9) was used, rather than pH 6 of deionized water.

Mikeska *et al.*<sup>17</sup> used 20 M HF at 90 °C and found a significant rate of penetration by the removal of the silicon phase through the formation of H<sub>2</sub>SiF<sub>6</sub>.

#### Sintered silicon carbides

In this form, silicon carbide is one of the most resistant of all ceramics to both acidic and basic aqueous-based

corrosion, and finds a wide range of applications, including components in paper-making plant, cement plants, and heat exchangers.

In water, sintered silicon carbide is quite stable up to ~400 °C, but at higher temperatures, hydrothermal decomposition can take place at the surface by the following reactions (Yoshimura *et al.*<sup>67</sup> working with powders):

The authors suggest that water diffuses faster than oxygen through the thin protective surface layer of amorphous silica that is always present, accelerating the reaction compared with the oxidation rate in dry air. The silica is progressively dissolved allowing further oxidation to occur. At lower temperatures, the removal of the silica by abrasive or sliding wear processes exposes fresh surface, which oxidizes, and this defines the rate of surface removal.

Acid attack on a sintered material (B and C sintering acids) has been shown by Genthe *et al.*<sup>68</sup> to be minimal at 240 °C, 168 h for HCl, HNO<sub>3</sub>, and HF, but significant in an HNO<sub>3</sub>/HF mixture

( $\sim 270 \text{ mg cm}^{-2}$ ) as a result of a combined oxidation and dissolution effect.

Marcus and Ahrens<sup>17</sup> have evaluated two forms of porous sintered SiC in 96%  $\text{H}_3\text{PO}_4$  at 204 °C, and found minimal rates of attack.

The alkaline corrosion resistance of two forms of sintered silicon carbide has been examined by Sato *et al.*<sup>69</sup> They found that there was sensibly no attack by up to 25 M NaOH held at up to  $\sim 200$  °C for 3 days. Above this temperature and up to 300 °C, there was still no attack, provided that there was no free oxygen, but in the presence of oxygen, attack became significant, the surface layer of the material becoming penetrated and minor grain boundary phases being removed, leading to a significant loss in strength. This process greatly increases the exposed surface area of silicon carbide, which is then attacked *via* a hydrolysis type reaction given earlier, the silica being dissolved by the alkaline solution. The authors fitted a shrinking core model to the depth of penetration observed.

#### Liquid phase sintered silicon carbides

Liquid phase sintering is a recent development for SiC compared with the other process methods, and has been exploited in an attempt to improve strength and toughness of a SiC-based material. Like the situation with silicon nitride (explained later), it involves the use of additives such as alumina and yttria to promote densification at high temperature, and leaves these components as a grain boundary phase on completion of the process. The corrosion resistance of this type of product has not been widely studied, but it is likely to be poorer than the solid-state sintered version with some penetration likely in strong acids and strong alkalis.

#### Chemical vapor deposited (CVD) SiC

Generally, one would expect CVD SiC to behave similar to the sintered versions. Kim *et al.*<sup>70</sup> have studied the behavior of CVD SiC in water at 360 °C in comparison with sintered material, and found that the former performed better. Under these conditions, slow grain-boundary attack occurred, leading to an initially parabolic weight loss with time, but after some days resulting in the loosening of surface grains with a step increase in mass loss.

Mikeska *et al.*<sup>17</sup> showed that this material has excellent resistance to HF at 90 °C, and recommended its use as a coating to protect other forms of SiC that corrode down grain boundaries.

#### Other SiC composites

The corrosion properties of particulate composite materials based on SiC/TiC mixtures with alumina as a sintering aid have been studied<sup>68</sup> using a range of acids. It was established that the attack rates were very low in concentrated HCl ( $\leq 4 \text{ mg cm}^{-2}$  after 168 h at 210 or 240 °C), most of the attack being surface removal of TiC. An HF and  $\text{HNO}_3$  mixture proved to attack an order of magnitude faster, probably because the SiC phase was also removed, while an HF/ $\text{HNO}_3$  mixture attacked yet another order of magnitude faster at only 100 °C in 24 h because of the synergistic effects oxidizing the SiC and removing the  $\text{SiO}_2$  formed.

#### 3.25.4.2.2 Silicon nitrides

##### Material types

Like SiC, there are several routes by which silicon nitride materials can be produced. The first materials were produced by *hot-pressing* with, typically, MgO, and although this method has been extensively used and data on test materials have been widely reported in the literature, this method is nowadays rarely used for technical products because of the cost and a lack of shaping flexibility. The other widely researched early method was *reaction bonding* in which a preform of powdered silicon was converted to silicon nitride by heating in nitrogen. This material has open porosity, and therefore, is seldom employed for its corrosion resistance except as a crucible material for high temperature melts. In recent decades, the focus has switched to *sintering* the material using additions such as alumina and yttria, although a whole range of more exotic sintering aids has been explored with the aim of maximizing high temperature performance, particularly oxidation and creep resistance. The sintering process is relatively complex, and usually requires an overpressure of nitrogen in order to suppress high temperature dissociation, known as *gas-pressure sintering*. An alternative process is to first use the reaction bonding process at  $\sim 1350$ – $1400$  °C on a silicon-based shape containing sintering aids, and then to raise the temperature to  $\geq 1750$  °C to induce the sintering process. Such products are usually termed *sintered reaction-bonded* silicon nitride. The lowest closed porosity levels in any sintered products, and hence the highest densities, often require *hot isostatic pressing*. Sometimes this is done as part of the primary fabrication route, and sometimes as a second operation. Some versions of sintered silicon nitride have optimized fracture

toughness through the development of elongated silicon nitride grains; products of this type are typically used for corrosion-resistant rolling bearings.

The term 'sialon' is used for materials in which the composition is adjusted such that a solid solution between alumina and silicon nitride is produced as the primary phase. The secondary phases contain sintering aids, and thus such products can be considered as rather similar to sintered silicon nitrides in most respects, including corrosion resistance. There is no defined boundary between the two types.

Silicon nitride in its purest state can be prepared by chemical vapor deposition, but is not widely available. Because of the absence of secondary phases, this material has better corrosion resistance than do materials containing secondary phases to aid sintering.

Composites between silicon nitride and other nonoxides have been developed, with additions of BN, TiB<sub>2</sub>, TiN, MoSi<sub>2</sub>, but these are outside the scope of this chapter.

### **Sintered silicon nitrides**

Perhaps the most detailed published ambient pressure study is that of Okada and Yoshimura,<sup>71</sup> who evaluated a dense gas-pressure sintered silicon nitride in boiling sulfuric acid. This material contained secondary components alumina and yttria, which form a grain-boundary phase that is, for the most part, continuous. Flexural strength and mass loss were determined as a function of time at a range of boiling acid concentrations. It was found that in a 1 h test, pH 3 solution boiling at 103 °C created the biggest loss in strength and mass, with higher concentrations have a lesser effect. In prolonged exposure, there was a progressive loss of mass and of nominal flexural strength, the latter attributable to the development of a weakened porous surface skin. After 72 h exposure to 6 N sulfuric acid at 105 °C, the strength had dropped from an initial level of  $888 \pm 57$  MPa to  $445 \pm 45$  MPa. Some of this drop may be attributable to the removal of residual stresses due to machining the original test-pieces. The surface layer thickness, as a measure of penetration rate, increased from 100  $\mu\text{m}$  after 24 h to more than 250  $\mu\text{m}$  after 72 h, approximating to a rate of  $\sim 3 \mu\text{m h}^{-1}$  after an initial transient, but without loss of physical cross-section. The mechanism of corrosion is not discussed, but is likely to be a simple dissolution process of the yttria part of the secondary phase, while the silicon nitride itself is not significantly attacked. This type of attack has also been reported by Lin *et al.*<sup>72</sup> and is likely to be found in most commercial

products with alumina and yttria as the sintering aids. Similar attack processes have been found for a material with yttria and lanthana as the sintering aids.<sup>73</sup> Products with alternative rare-earth additions rather than yttria are likely to be more corrosion resistant. Fang *et al.*<sup>18</sup> show that a sintered sialon material with a glassy second phase is reasonably resistant to corrosion by a 1% HF + 5% HCl solution.

Sato *et al.*<sup>74</sup> tested a series of hot isostatically pressed silicon nitrides containing Y<sub>2</sub>O<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub> sintering aids in 1 M HCl at 70 °C for 50–240 h. Analysis of the test solution showed that Al and Y dissolved preferentially from the grain boundary phase, and that retained strength progressively reduced with ageing time. It was further found that when the solution concentration was less than 1 M, the corrosion rate was controlled by the reaction at the surface, and when greater than 5 M, the rate was determined by diffusion through the corrosion product layer. In a material containing no additives, no attack occurred.

Sato *et al.*<sup>75</sup> have compared the rates of attack of a 25 M NaOH solution at 150–200 °C for 3 days on hot-pressed and sintered silicon nitrides of similar composition, both containing Al<sub>2</sub>O<sub>3</sub> and Y<sub>2</sub>O<sub>3</sub> as densification aids. It was found that the rate of attack in terms of mass loss was low at 150 °C, but at higher temperatures, the sintered material with 5.2 wt% additions was attacked more rapidly than was the hot-pressed material with 4.7 wt% additions. This was ascribed to the preferential dissolution of silica. However, the hot-pressed material lost strength in a more catastrophic way with a total weight loss greater than in the sintered material, although the reasons for this are not entirely clear.

Sato *et al.*<sup>76</sup> have reported experiments on three materials with differing grain boundary phase compositions, conducted under neutral hydrothermal conditions (200–300 °C) for 3 days. A white deposit developed on the surface of the material, which was found to contain hydrated silica and grain boundary phases of alumina and yttria. The material in which this phase remained glassy appeared to perform better than those in which it is partially crystallized. Strength was found to drop from an initial 630 MPa toward 400 MPa.

### **Reaction-bonded silicon nitride**

Being open-porous, this material is not widely used for liquid environments at low temperature, and therefore, few data are reported, but if substantially

free from impurities, it will, like hot-pressed and some sintered versions, show good corrosion resistance to acids. Marcus and Ahrens<sup>7</sup> report minimal rates of attack in  $\text{H}_3\text{PO}_4$  at 204 °C.

### 3.25.4.2.3 Boron nitrides

#### Material types

Boron nitride exists in two forms: the crystallographically cubic form (CBN) is akin to diamond in properties, while the hexagonal form (HBN) is akin to graphite. CBN is difficult to densify, but is made in monolithic form as a cutting tool and die material. In contrast, HBN is available as a hot-pressed, machinable form for general applications, and via a vapor phase route, when it is usually termed 'pyrolytic.'

#### CBN

CBN is widely claimed to be corrosion resistant, but no specific information is available at this time. The binder phase employed to aid the compaction process is likely to control performance.

#### HBN

Corrosion performance is limited by a hydration process that converts BN to boric acid with the release of nitrogen. Oda and Yoshio<sup>77,78</sup> have shown that the rate of attack on a solid material under hydrothermal conditions (150–300 °C, 1–10 days) is related to crystal orientation, because the oriented grains in pyrolytic material are attacked more slowly than the more randomly orientated hot-pressed material, as shown by micrographic evidence. Figure 7 shows their results for the linear portions of the trends of mass loss as function of time, ignoring an initial

transient. The activation energy for the hydrolysis process was computed as 60 kJ mol<sup>-1</sup>, based on equivalent tests on powdered material.

Moderate rates of attack by both acids and alkalis were found in NPL tests at 140 °C/23 h. Marcus and Ahrens<sup>7</sup> report moderate rates of attack at 204 °C in  $\text{H}_3\text{PO}_4$ .

### 3.25.4.2.4 Specialist materials

AlN – Young and Duh<sup>79</sup> report that corrosion rates at room temperature in alkaline solutions are much faster than in neutral or acid solutions as a result of a catalyzed hydration process with the formation of aluminates as intermediaries. Marcus and Ahrens<sup>7</sup> report rapid dissolution in  $\text{H}_3\text{PO}_4$  at 204 °C.

TiC – Genthe *et al.*<sup>68</sup> have tested hot-pressed material, and shown some slow acid attack in HCl and HF, but rapid attack in  $\text{HNO}_3$  and HF– $\text{HNO}_3$  mixture.

TiB<sub>2</sub> – Monticelli *et al.*<sup>80</sup> demonstrate that hot-pressed material with 1.5% Ni behaves like a passive metal in 3.5% salt solution at 25–65 °C, with the formation of a corrosion-resistant TiO<sub>2</sub> layer on the surface. However, tests at NPL have shown that hot-pressed material is rapidly attacked by acids at 140 °C/23 h, especially HCl, but is very resistant to KOH solutions. Marcus and Ahrens<sup>7</sup> showed that a hot-pressed material was attacked faster than a sintered material in  $\text{H}_3\text{PO}_4$  at 204 °C.

MoSi<sub>2</sub> – Marcus and Ahrens<sup>7</sup> report slow attack by  $\text{H}_3\text{PO}_4$  at 204 °C.

B<sub>4</sub>C – NPL tests have shown negligible attack by acids and alkalis at 140 °C/23 h on a hot-pressed material, except an  $\text{HNO}_3$  +  $\text{H}_3\text{PO}_4$  mixture, which gave slight attack. Mikeska *et al.*<sup>17</sup> report minimal

Figure 7 Hydrolysis of dense boron nitride as a function of temperature.<sup>77,78</sup>

attack by HF at 90 °C. Marcus and Ahrens<sup>7</sup> report negligible attack rates by H<sub>3</sub>PO<sub>4</sub> at 204 °C.

Pure WC, CaF<sub>2</sub>, MgF<sub>2</sub> show excellent resistance to HF at 90 °C.<sup>17</sup>

### 3.25.4.3 Comparative Attack Rates

From the foregoing, it will be appreciated that the performance of any one material is highly dependent not only on its composition and microstructure, but also on the conditions to which it is subjected and how the effects of corrosion are measured. It is therefore particularly difficult to give a clear appreciation of the comparative performance of the huge range of materials now available. There are relatively few sources of directly comparative numerical data over a wide range of products. Some appreciation can be obtained from unpublished NPL work<sup>13</sup> given in Figure 8.

## 3.25.5 Some Specific Applications Requiring Corrosion Resistance

### 3.25.5.1 Chemical Process Vessels

There has been a long history of the use of technical ceramics for chemical process vessels, both as the lining and as furniture inside them. If the vessels are limited in dimensions to typically 500 mm or less,

they can be made from monolithic shells of dense, chemically resistant porcelain, which provide a long life except perhaps with the most aggressive of reagents. Examples include digesters and ball mills. If the vessels are larger, a lining of chemically resistant brickwork is required, usually bedded into a chemically resistant mortar. The mortar may be the life-limiting factor, but despite this, successful applications have been achieved for many years. A review of such applications may be found in Charlebois.<sup>5</sup>

Furniture, such as so-called 'tower packing,' is often made from a chemically resistant stoneware, a product much coarser in texture than porcelain, but with similar properties, provided that the as-fired surface skin remains intact. This skin acts as a glaze, which seals access to internal porosity. In some aggressive environments, their successful application may be reliant on preservation of the skin. More expensive options rely on alumina ceramics, but these tend to be available only in rather smaller pieces. Other applications reliant on alumina include filter plates, filters, nozzles, pipe linings, etc.

In the laboratory, chemical porcelains continue to be used for pestles, mortars, and other corrosion-resistant parts for chemical handling. Low thermal expansion glass-ceramics are used for hot-plate and stirrer plate units, minimizing the risks of corrosion from common chemicals. Similar materials are used in the kitchen for cookware and for cooker hobs.

**Figure 8** Comparative rates of mass loss after exposure in PTFE-lined digestion bombs to various 20% by volume solutions at 140 °C for 23 h.

### 3.25.5.2 Rotating Seals

Rotating seal faces for pumps are usually made from a hard material such as a ceramic and an abradable material, often carbon or graphite based. Alumina ceramics are the most commonly employed hard faces for water and organic liquid-based media, and have demonstrably long lives in the absence of excessive abrasion or very high or very low pH. Examples include central heating pumps, light-duty chemical process pumps, and food processing pumps. Where there is additional loading, such as abrasive particles, a harder material is usually employed, such as silicon carbide. For vehicular water cooling pumps, silicon nitride has been widely used because of its better strength and thermal shock resistance compared with alumina.

For highly acidic conditions, secondary phases in alumina limit corrosion/abrasion performance and silicon carbide-based materials are often employed.

Silicon carbide is also often the material of choice in gas bearings and gas pump seals.

### 3.25.5.3 Flow-meter Bodies

Flow-meters for highly corrosive chemical plant circuits based on electroconduction are typically made from alumina ceramics. Insulated electrodes can be sealed through the wall to provide the sensing circuit, and provided that the right choice of material is made, the life can be much longer than that of the attached pipework.

### 3.25.5.4 Food Processing

The linings of food processing equipment can often, with advantage, be made from alumina ceramics, which resist corrosion from food acids as well as abrasion. Food is not contaminated in the same way as it might be with metallic linings such as stainless steel. The key requirement is that the materials withstand typical chlorinated steam cleaning processes, which can be more aggressive than the food itself. Materials with good resistance to hydrochloric acid at elevated temperatures are required.

### 3.25.5.5 Valves

Seal faces for valves, including shower mixers, quarter-turn faucets, gas valves, etc., are typically made from pairs of alumina ceramics plates with flat lapped faces. These resist corrosion from normal

water supplies to elevated temperature, and have a long, corrosion-free life that is usually limited only by risks of mechanical damage from the metallic components used to operate them, or from the deposition of lime-scale, which can jam them, or lead to excessive wear.

Corrosion-resistant ball valves used for chemical plant are also made typically up to 150 mm diameter. The choice of material for this application is critical, as in the case of flow-meters.

### 3.25.5.6 Medical

The human body places unusually corrosive conditions on materials used for implants, but because of their corrosion resistance, ceramics are successfully being employed for both dentistry and orthopedics. In the mouth, glassy porcelains are used for individual tooth crowns, and the literature contains increasing number of reports of the use of machinable glass-ceramics for forming tooth shapes, and of zirconia (Y-TZP type) for prosthetic bridges. For orthopedics, the combination of strength and corrosion resistance of, particularly, alumina is exploited for balls and cups for hip replacement. Zirconia (Y-TZP type) has also been used, and offers higher mechanical strength, but as described earlier, there are some potential limitations of phase stability at body temperature. Increasingly, alumina-zirconia composite materials are being employed to overcome the instability problem, and silicon nitride is on the horizon, already widely employed for rolling bearing balls.

Other corrosion-resistant ceramics used in the body include glassy carbons for heart valves, and hydroxyapatite as a fully biocompatible ceramic, which can be used as a coating on metallic components to enhance osseointegration, or as a free-standing material to assist in bone reconstruction. Bioglasses and bioglass-ceramics also have specialized applications in which reaction with the body is deliberately exploited in their function.

## 3.25.6 Selecting the Right Material

It is hard to predict performance, and, therefore, it is important when selecting ceramic materials for corrosion-resisting applications to undertake some relevant testing to check potential performance, unless there is direct previous experience with a particular type of product. Often, ceramic materials are not specifically optimized for applications

requiring corrosion resistance, and may contain species that are readily removed. Simple ranking tests will provide a guide, as in [Figure 8](#).

In addition, there are other factors which may dictate material choice, including price, availability in the shape and dimensions required, aspects of mechanical performance, and aspects of joining to other components. For those not experienced with the use for ceramic components, specialist advice should be sought.

## Glossary

**Glass** A solid material that is characterized by lack of crystallinity; that is, with short-range but not long-range order.

**Glass-ceramic** An initially glassy material that, when heat-treated, forms a crystalline phase such that the material, on cooling, comprises a composite containing the crystalline phase surrounded by the remaining glassy material; such materials generally have enhanced mechanical properties compared to either a typical glass or a typical ceramic of similar composition.

**Network former** A compound such as silica ( $\text{SiO}_2$ ) that, when cooled at a sufficient rate, will on its own form a glass.

**Network modifier** A compound such as soda ( $\text{NaO}$ ) or calcia ( $\text{CaO}$ ) that will not form a glass on cooling and, when combined with a network former, will disrupt network bonds.

**Static fatigue** The process of delayed fracture below the normal fracture stress of a glass that results from cracks growing from flaws on the glass surface, usually exacerbated by the presence of moisture or humidity.

**Vitreous** The glass-like state of a material that might otherwise crystallize (e.g., vitreous silica is the glassy state of the compound  $\text{SiO}_2$ , while quartz is one of the crystalline phases of the same compound).

### 3.26.1 Introduction

One of the most important properties of commercial glasses is their great resistance to corrosion; any chemical laboratory apparatus, window, or wind-screen provides an excellent illustration. Windows remain virtually unchanged for centuries, resisting the influences of atmosphere and radiation. A vast range of products may be safely stored in glass for decades at ordinary temperatures, and the fact that glass can be used with alkaline, neutral, and acid environments allows the same equipment to be used for a variety of processes.

The principal difficulty associated with the use of glass equipment is the fact that glass fractures rather than deforms on severe impact. Thus, although it may be toughened by thermal treatment or ion exchange,

glass remains a material that has intrinsically a relatively low value of fracture toughness and small critical flaw size. Glass is also more prone than metals to damage by thermal shock, although this difficulty can be largely avoided by the use of low-expansion glass formulations. Finally, the size of glassware that can readily be fabricated is sometimes below the needs of a particular process.

### 3.26.2 Commercial Glasses

The term glass defines a family of materials that exhibit as wide a range of differences among themselves as exists among metals and alloys. The great variety of physical and chemical properties available arises from the possibility of including almost all the stable oxides, sulfides, halides, etc. throughout the periodic table in different glass formulations. Many branches of the family, for example, those borates, silicates, and phosphates which are water-soluble, are of little interest in the present context. It is, however, worth bearing in mind that glasses can be designed to combine particular physical properties with good chemical resistance.

For most of the commercial oxide glass families, silica ( $\text{SiO}_2$ ) is the main ingredient. However, lower melting points and greater flexibility of properties are achieved with the addition of other oxides and modifiers. Depending upon the choice of these additional constituents, glasses are classified into groups, including fused silica, soda-lime glasses, leaded glasses, aluminosilicate glasses, borosilicate glasses, etc. A cross section of some commercial glass compositions is given in [Table 1](#).<sup>1</sup>

*Fused silica* is a general classification within which is a range of varieties and types of material with differences in purity, transmission, and grade. This type of glass may be used up to 900 °C in continuous service; it resists attack by a great many chemical reagents, rapid attack occurring only in hydrofluoric acid and concentrated alkali solutions.

*Container glass* is suitable for the storage of beverages, medicines, cosmetics, household products, and a wide range of laboratory reagents.

*Tubing glass* is suitable for general laboratory use and chemical apparatus construction, though neutral or hard borosilicate are preferred for more severe conditions, these representing the most resistant glasses available in bulk form.

*Neutral glasses* are generally less resistant than the hard borosilicate type, but are more easily melted

1, fused silica; 2, window glass; 3, container glass; 4, fluorescent tubing; 5, neutral glass; 6, hard borosilicate; 7, lead glass; 8, TV tube and screen; 9, textile glass fiber; 10, glass wool insulation; 11, superfine glass wool.

and shaped. They are formulated so that the pH of aqueous solutions is unaffected by contact with the glass, making it particularly suitable in pharmaceutical use for the storage of pH-sensitive drugs.

*Borosilicate glasses* are, in terms of different types available, the most versatile types of glass produced. In general, borosilicate glasses are grouped into five types: low-expansion glass, low electrical-loss glass, materials for seals to metals, glasses for laboratory apparatus, and optical-grade glasses, including those with enhanced transmission beyond the visible spectrum. The example given, that is, hard borosilicate glass, is typically used for ovenware, laboratory apparatus, etc., and combines low expansion and high chemical resistivity with chemical stability. These types of glasses generally require high fabrication temperatures compared with soft soda glasses.

*Electronic grade glasses* are used in cathode ray tube screens and similar applications, and contain higher quantities of heavy elements (e.g., lead, barium, etc.) in order to absorb radiation. These glasses do not operate under severe corrosion conditions, but surfaces must not leach excessive alkali under damp conditions or electrical breakdown can occur.

*Glass fibers* present particular problems in corrosive environments because of their very high surface/volume ratios. Glasses for electrical insulation are generally formulated from alkali-free aluminoborosilicate glasses (generally known as E-glass) and are frequently specified as containing less than 1% alkali (Na<sub>2</sub>O and K<sub>2</sub>O). This type of glass is also used extensively for the reinforcement of plastics where its high resistance to moisture attack ensures a durable product.

*Glass wools* are used for less demanding applications and generally contain some alkali to aid in processing. Superfine wool contains zirconia and titania to enhance the chemical resistance while retaining the properties necessary for economic fine fiber formation.

### 3.26.3 Physical Properties

#### 3.26.3.1 Structure

Glass has been defined as 'an inorganic product of fusion which has cooled to a rigid condition without crystallizing.' The atomic structure of glasses is more closely related to liquids than to crystals. The properties of glasses are manifestations of this structure, being governed in particular by the random liquid-like disposition of the network-forming ions (commonly Si<sup>4+</sup> and B<sup>3+</sup>); the presence of mobile, interstitial alkali ions; and the 'single-molecule' nature of the lattice. The bonding within the atomic network is partly covalent and partly ionic. Thus, the network bonds are highly directional with a range of interbond angles, bond lengths, and bond energies; the bonding electrons are restricted to particular energy levels within the bonds. The network-modifying ions (commonly alkali and alkaline-earth ions) are ionically bound to the network although the field strength and diameter of the alkali ions allow them some mobility as a function of temperature.

The random nature of the glass structure imparts a range of bond energies in the network, and hence a characteristic feature of glasses is a continuous

softening over a range of temperature, a continuous viscosity/temperature curve, and the absence of a true melting point. For convenience in comparing the viscosity behavior of different glasses, arbitrary temperatures at which the glass has specific viscosities are often quoted.<sup>2</sup> The Littleton softening point<sup>3</sup> is most commonly used. At this temperature, the glass has a viscosity of  $10^{6.6}$  Pa s.

The glass transition temperature  $T_g$  corresponds to a viscosity between  $10^{12}$  and  $10^{13}$  Pa s depending on the definition and on the method of measurement. Glass behaves as a Newtonian liquid at temperatures well above the glass transition. It is this behavior that prevents the necking generally observed during plastic deformation of metals and which allows glass to be easily formed into such a large number of useful configurations.

In practice, an important range of viscosities are those from  $10^{11}$  to  $10^{13.5}$  Pa s, known as the annealing range. The annealing point and the strain point are generally taken as the temperatures at which the glass has a viscosity of  $10^{12.4}$  and  $10^{13.6}$  Pa s, respectively. Within this range, the glass is effectively a solid, but internal stresses can be relieved within a practical time scale. Rapid cooling of glass articles through the annealing range eventually results in permanent and sometimes catastrophic thermal stresses. However, it is possible to cool the glass relatively quickly from the lower end of the annealing range.

The structural features are reflected in the characteristic properties of inorganic glasses and bring about a broad overall similarity in behavior as summarized below. Values for the physical properties of the glasses listed in Table 1 are given in Table 2.

### 3.26.3.2 The Nature of the Glass Surface

It is widely accepted that the composition of the surface of a glass is different from that of its interior.

Alkali loss during forming, grinding, polishing, and surface treatments affects the structure of the surface, but a more basic difference is brought about by the effect of the unbalanced force fields at the surface on the ions within the glass.

Glass is composed of glass-forming cations (e.g.,  $B^{3+}$ ,  $Si^{4+}$ ,  $P^{5+}$ ) surrounded by polyhedra of oxygen ions in the form of triangles or tetrahedra. Two types of oxygen ions exist: bridging and nonbridging. The former, bonded to two network-forming ions, link polyhedra, and the latter, bonded to one network-forming ion only, carry an excess negative charge. To compensate for this, charged cations of low positive charge and large size (e.g.,  $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ ) are located within the structure. Silicon may be substituted by other cations of large positive charge and small size; these are collectively known as network formers.

The difference in size and field strength between ions is reflected in the polarizabilities of each ion and their final position relative to the glass surface. Since the force field is unbalanced, ions of low polarizability will remain near the surface and ions of higher polarizability will move towards the interior of the glass. A strong feature of chemical reactions associated with the surface is the need to screen adequately (and not merely to neutralize) those cations that have strong electric fields. If the unbalanced field is removed by the presence of materials, liquid, adsorbed vapor, or solid in contact with the glass, there is sufficient mobility within the glass surface zone for it to revert to a more normal structure by the diffusion of ions towards the surface.

### 3.26.3.3 Thermal Expansion

Glasses having coefficients of linear thermal expansion of from  $5 \times 10^{-7}$  to over  $10^{-5} K^{-1}$  are available. However, high-expansion glass compositions do not

**Table 2** Physical property data for the glasses of compositions listed in Table 1<sup>1</sup>

generally have long-term chemical durability. Glass-ceramic materials, on the other hand, are remarkable for the very wide range of thermal expansion coefficients that can be obtained. At one extreme, materials having negative coefficients are available, while for other compositions very high positive coefficients can be obtained. Between these two extremes, there exist glass-ceramics having thermal expansion coefficients practically equal to zero and others whose expansion coefficients are similar to those of ordinary glasses or ceramics or to those of certain metals and alloys and, hence, allow thermal compatibility. This range of expansion coefficients is allied with good chemical durability.

### **3.26.4 Mechanical Properties**

Characteristically, glasses are susceptible to brittle fracture under tension but tend to have significantly higher compressive strengths. The ionic and directional nature of the bonds and the localization of bonding electrons to pairs of atoms preclude bond exchange. This, coupled with the random nature of the atomic lattice, that is, the absence of close-packed planes, makes gross slip or plastic flow extremely difficult.

#### **3.26.4.1 Strength**

If flaws and stress concentrators, which emphasize the brittle nature of glass, can be avoided, then a glass article behaves as though its strength is governed by the high interatomic bond strength. Glasses are therefore inherently very strong materials, theoretically capable of exhibiting a tensile strength of about 7 GPa. In practice however, surface flaws act as stress concentrators under tensile loading, and commercial glasses in bulk show a mean strength in tension of only about 40 MPa. The statistical variation of strength about this figure makes it desirable to allow a substantial safety margin and to design using a figure of about 7 MPa.<sup>4</sup>

The strength of glass can be increased to about 200 MPa by commercial (generally thermal) toughening processes. The use of such glasses is not possible, however, at elevated temperatures since resoftening will occur. Undamaged commercial glass fibers display strengths of about 2 GPa, which is dependent upon surface protection, given usually by organic coatings. Removal of the coating results in a marked decrease in strength due to the introduction of small surface flaws.

#### **3.26.4.2 Elastic Modulus**

Up to the fracture stress, glass behaves, for most practical purposes, as an elastic solid at ordinary temperatures. Most silicate-based commercial glasses display an elastic modulus of about 70 GPa, that is, about one-third the value for steel. If stress is applied at temperatures near the annealing range, then delayed elastic effects will be observed and viscous flow may lead to permanent deformation.

The brittle nature of glasses at normal temperatures makes them inappropriate for use in locations where severe impacts are likely to be encountered. In the design of pipelines or other equipment, it is possible to use normal engineering assembly techniques provided that suitable gaskets or cushioning are provided at joints and supports and that care is taken in tightening bolts to avoid unequal or localized stresses.

#### **3.26.4.3 Thermal Shock Resistance**

The ability of a glass article to withstand sudden changes of temperature depends primarily on its thermal expansion coefficient, its thickness, and its design. For articles of identical shape, a low-expansion glass (such as a commercial borosilicate) will withstand appreciably greater temperature shocks than will glass of a higher expansion coefficient. Thermal shock-resistance testing is usually carried out by transferring the articles from a hot environment to a cold vessel containing water at a predetermined temperature.<sup>5</sup> In general, transitions from a hot to a cold environment are more likely to produce failure than those in the opposite direction since they tend to induce tensile stresses at the surface.

### **3.26.5 Chemical Properties**

#### **3.26.5.1 Degradation**

Technical glasses are now used so extensively and in such widely varying circumstances that it is necessary to be as accurate as possible in describing their chemical properties. The deterioration of individual glasses is dependent on composition, manufacture, and use and, unless the degradation processes are accelerated, may be observable only after very long periods of time. A typical figure for the corrosion rate of an ordinary soda-lime-silica glass would be less than  $10 \mu\text{m year}^{-1}$ . The effect is accelerated when the exposure takes place at higher temperatures, for example, in boiling

**Table 3** The corrosion resistance for commercial glasses listed in Table 1

	Glass				
	1	2	3	6	7
Water	A	B	B	A-B	B-C
Acid	A	B	B	A-B	B-C
Weathering	A	C	C	A-B	B-C

A, essentially resistant; B, possibility of degradation; C, certain degradation.<sup>1</sup>

water or in an autoclave. Table 3 compares the corrosion resistance of some commercial glasses.

One of the most commonly used measures of durability, that is, loss of sodium from the glass, is important to the pharmaceutical and chemical industries, but other changes such as loss of surface quality, are of equal importance for optical and window glasses. The properties of a wide range of technical glasses are well catalogued,<sup>5-7</sup> but the data are often inadequate when considering a particular application and where possible nonstandard 'whole article' tests are advisable.

### 3.26.5.2 Glass Durability Tests

In selecting a glass for chemical durability, regard must be paid to the temperature and concentration of the corrosive agent, length of exposure, ratio of reagent volume to surface exposed, and mechanical operating conditions. Guidelines on the durability of many commercial glasses in some attacking media are available from standard durability tests. There are two types of durability tests for glassware: 'grain' or 'powder' tests and 'whole article' tests.

#### 3.26.5.2.1 Grain tests

In these tests, samples of glass crushed and graded to a specified sieve size are exposed under standard conditions of time and temperature to the attacking medium. The temperatures commonly used are 98 °C (water bath) and 121 °C (autoclave) and the attacking media are water, acid, and alkali. The amounts of a particular glass constituent (usually soda or total alkali) removed from a standard weight in a given time are determined. Various standard test methods have been established.<sup>8-11</sup> However, variability is found between different laboratories, and using a particular grain test has shown considerable divergence, and it appears that

to obtain consistent results very close adherence to the details of the standard procedures is necessary.<sup>12</sup>

#### 3.26.5.2.2 Whole-article tests

Grain tests are open to the criticism that they do not necessarily reflect the behavior of the finished product in service, and hence various tests on complete glass articles have been developed. These are normally carried out under accelerated conditions, and on completion various relevant factors are determined, such as loss in weight, alkali or other constituents extracted, the weight of soluble and insoluble materials in the extract, and an assessment of surface condition. Analytical microscopy and other surface analytical tools can be of great assistance in determining mechanisms.

Whole-article tests are particularly useful in the evaluation of window and optical glasses. Various tests have been proposed for window glass, but no standards exist. The usual procedure is to subject the glass to an accelerated humidity/temperature weathering cycle and to assess the surface conditions after a given period of treatment. The degree of haze formation has been suggested as a method of measuring surface damage, but generally visual comparison with a standard is used. Figure 1 illustrates the application of such a test to various optical glasses.

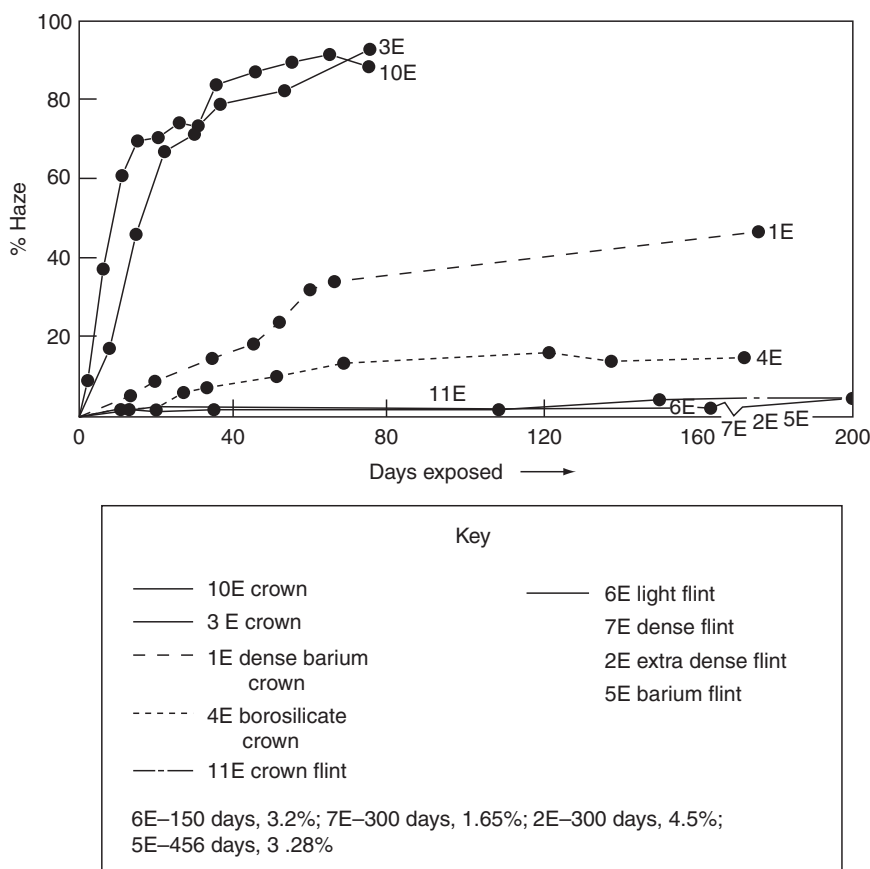

Many optical glasses are much less resistant to attack than are container and window glasses, and less severe tests are necessary. A commonly used method is to immerse specimens in either dilute nitric acid or standard acetate solution (pH 4.6) for specified periods at room temperature, and then to examine the surfaces.

Glass fibers present a particular problem in that the resistance of the base glass is unlikely to be representative of the performance of the final product. Generally, empirical methods are used to test the glass fibers *in situ* in a composite material: for example, the fibers are made up into rods or rings with the appropriate partly polymerized plastic; the composites are then cured under specified conditions; and the breaking strength is determined after various exposures to water or steam.

## 3.26.6 Mechanisms of Glass Corrosion

### 3.26.6.1 General Properties

Glass surfaces may react with corrosive agents in one or a combination of the following ways:

**Figure 1** Comparison of optical glasses after exposure to an alkaline solution. Simpson, H. E. *J. Soc. Glass Technol.* **1953**, 37, 249; *J. Am. Ceram. Soc.* **1953**, 36, 143-146.<sup>13</sup>

- by forming new compounds on the surface;
- by selectively losing material from a leached porous layer;
- by continuous dissolution leaving a freshly exposed surface.

Important effects on glass durability in aqueous conditions, due to the interrelation between glass composition and environmental pH, have been reviewed by Doremus<sup>14</sup> and Adams.<sup>15</sup> To some extent, durability can be predicted on thermodynamic grounds.<sup>16,17</sup> In general, additions of CaO (calcia) and Al<sub>2</sub>O<sub>3</sub> (alumina) to a basic alkali silicate glass confer water resistance; additions of zirconium, lanthanum, tin, and chromium oxides improve alkali resistance; and reducing the levels of boron, aluminum, or lead oxides, in glasses where they are present, improves acid resistance. Predictions of the effects of added oxides on glass durability should, however, be treated with caution. Structural factors, such as

occurrence of phase separation, coordination state, mixed alkali effect, and/or kinetic effects resulting from the presence or absence of insoluble reaction product layers on the glass surface, can influence durability to a significant extent.

More generally, Valez *et al.*<sup>18</sup> have reviewed the corrosion behavior of silicate and borate glasses in contact with alkali metals and molten salts, as well as in aqueous conditions.

Another important aspect of glass corrosion behavior that should be emphasized is the effect of applied stresses. Glass is subject to stress-enhanced corrosion, which is often described as static fatigue. Under a continuously applied stress, and in the presence of normal environmental moisture (or other more aggressive corrosion conditions), cracks may grow from flaws on the glass surface and this can lead to delayed failure at stresses below the strength level that is measured in a short-term loading test.<sup>17,19</sup> As a consequence, common silicate glasses are usually expected to have a

load-bearing capacity at one-quarter to one-third the short-term strength when continuously loaded over some 50 years in the normal atmosphere.

### 3.26.6.2 Corrosion Mechanisms

There is no serious challenge to the view that the alkali or alkaline-earth ions are removed from glass in water by an ion exchange process in which  $H^+$  ions diffuse into the glass to preserve the electrical neutrality of the system. However, only under certain circumstances can the rate-controlling process be directly related to the diffusion of sodium in the glass. Most glass/corrosive agent systems are treated as unique cases, since in addition to the concentration of the attacking agent, temperature, rate of flow, and reaction time contribute to what is observed. General chemical principles of electrophilic and nucleophilic types of general attack can be applied to glasses.<sup>20</sup> The first is considered as an attack on nonbridging oxygen atoms by reagents with an electron deficiency and the second as an attack on bridging oxygens by reagents with an electron excess.

For the most common series of corrosive agents – water, steam, acids, alkalis, and salts – the hydrolytic processes peculiar to each determine the mechanism of attack. Thus, under the right circumstances, hydrolytic attack on bridging oxygen atoms can occur, which is an irreversible reaction resulting in permanent damage to the glass network. The corrosion process is modified by the physical state of the surface. Grinding and polishing processes, in particular, leave the structure with a degree of roughness and residual stress; all can contribute to accelerated corrosion.

### 3.26.6.3 The Action of Water and Acids

During attack, the alkali and alkaline-earth network-modifying ions are exchanged by  $H^+$  or  $H_3O^+$  from an acid solution. In some glasses the exchange process can go to completion causing only a small degree of network damage. In water, the exchange process proceeds at a very much slower rate relative to the acid conditions, and some attack of the network is possible as a result of the presence of alkali ions from the glass moving into solution. This is most pronounced when glass is attacked by steam at high temperature and where there is no mechanism for the removal of alkali from the hydrolyzed zone. Acid solutions mitigate this form of attack by neutralizing the alkali as it is formed.

The attack of most glasses in water and acid is diffusion controlled, and the thickness of the porous

layer formed on the glass surface consequently depends on the square root of the time. There is ample evidence that the diffusion of alkali ions and basic oxides is thermally activated, suggesting that diffusion occurs either through small pores or through a compact body. The reacted zone is porous and can be further modified by attack and dissolution, if alkali is still present, or by further polymerization. Consolidation of the structure generally requires thermal treatment.

### 3.26.6.4 Attack by Alkali Solution, Hydrofluoric Acid, and Phosphoric Acid

A common feature of these corrosive agents is their ability to disrupt the network. This process is not encumbered by the formation of porous layers, and the amount of leached matter is linearly dependent on time. Consequently, the extent of attack by strong alkali is usually far greater than either acid or water attack. Both  $HF$  and  $H_3PO_4$  form compounds of silicon as a result of attack on the network: silicon fluoride from hydrofluoric acid and silicic phosphate from phosphoric acid.

### 3.26.6.5 Chemical Attack by Other Agents

If the hydrogen ion concentration is sufficiently high, the glass loses a substantial amount of weight by leaching, but these reactions are dependent on the nature of the ions in solution. Certain salts, especially those of  $Zn$ ,  $Al$ , and  $Be$ , if present as trace amounts, can have a beneficial effect by poisoning the process and limiting the occurrence of leaching.

### 3.26.6.6 Cleaning of Glass

There is no universally ideal technique for either cleaning glass or avoiding contamination of the surface. In the most severe circumstances of corrosion, the only methods capable of restoring an acceptable surface finish consist of grinding and polishing or removing the contamination and corroded layers by strong etching agents such as hydrofluoric acid. Less severe conditions may respond to treatment by various detergent solutions or organic solvents, these being considerably aided by ultrasonic vibration. Manual washing or ultrasonic cleaning can be used to remove massive dirt accumulations. Vapor solvent degreasing processes, for example using isopropyl alcohol, has minimal corrosive action on the glass.

To restore old stocks of corroded glass, treatment in hot 1% sodium hydroxide solution followed by

rinsing in 5% hydrochloric acid and a final rinse in pure water at room temperature is recommended.<sup>21</sup>

### 3.26.6.7 Applications

Over recent years, a number of new applications of glasses have grown out of increased understanding and control of glass corrosion behavior. Conventional silicate and borosilicate glasses are subject to severe corrosive attack in highly alkaline solutions (pH 12–13.5), such as those found in Portland cement, and there is rapid and drastic loss of strength in fibers formed from soda or borosilicate compositions. To counter this, alkali-resistant glass fibers have been developed from silicate glass compositions and containing about 16 wt% of zirconia<sup>22,23</sup> and these have formed the basis for development of a range of glass-fiber reinforced cement (GRC) materials, analogous to glass-fiber reinforced plastics (GRP). In the GRP field, it has been shown that E-glass borosilicate fibers are prone to strength loss and stress corrosion in acidic environments<sup>24,25</sup> – this in turn led to the development of an acid-resistant version of E-glass for use in such conditions.

## 3.26.7 Vitreous Silica

Vitreous silica, also referred to as quartz glass, fused quartz, or fused silica, is a material of considerable importance, possessing a unique combination of high softening temperature, excellent resistance to chemical attack, and high transparency. Its general, physical, and mechanical characteristics are common to all glasses, the difference being that the high purity (>98.7% SiO<sub>2</sub>) maximizes the durability, fusion temperature, and volume stability. The general superiority of the properties of fused silica over conventional glasses is well illustrated in [Table 1](#). It has excellent high temperature properties in excess of 1000 °C, high resistivity, high chemical stability, and excellent thermal shock resistance due to its low coefficient of expansion. However, the high softening point makes it much more difficult to fabricate than conventional glasses.

### 3.26.7.1 Manufacturing

The raw materials for the production of vitreous silica are either high-purity rock crystal from which the transparent form is produced, or vein quartz (high-grade glass sand) from which impurities have

been removed by acid leaching. The persistence of liquid and gaseous inclusions is partly responsible for the translucency of cheaper forms of vitreous silica. Ground quartz is melted at around 2000 °C by induction heating in a graphite crucible. Even at this temperature, the melt viscosity is so high (10<sup>5</sup>–10<sup>6</sup> Pa s) that trapped gas bubbles do not float to the melt surface and can only be removed by vacuum treatment. At high temperature, the SiO<sub>2</sub> partly dissociates to the monoxide SiO, which is volatile.

Vitreous silica produced by this route contains small amounts of impurities such as Fe, Cr, Al, and Ca. These may be removed by reaction to form volatile metal chlorides, whereupon the remaining SiCl<sub>4</sub> can be hydrolyzed in a flame to produce fine molten droplets of SiO<sub>2</sub> which then deposit on a cold base; impurity levels below 10<sup>−7</sup>% can be reached in this process and are essential in applications such as optical fibers.

### 3.26.7.2 Structure and Physical Properties

#### 3.26.7.2.1 Polymorphism of silica

Although vitreous silica is nominally a homogeneous isotropic amorphous material, and should normally remain so during its service life, it is in fact in a metastable condition. The tendency to revert to crystalline forms with attendant deterioration in mechanical durability places severe limitations on the range of applications. [Figure 2](#) illustrates the polymorphic forms of silica, and the dimensional changes accompanying each transition.

Changes from one polymorphic form of crystalline SiO<sub>2</sub> to another, as from tridymite to quartz at temperatures below 870 °C and to cristoballite above 1470 °C, involve the breaking of Si–O bonds. High energies are required for these ‘reconstructive’ changes, and changes from one form to another require very long periods for completion. On the other hand, inversions from high- to low-temperature forms of quartz or cristoballite involve only changes in the angles between adjoining SiO<sub>4</sub> tetrahedra, and these ‘displacive’ transformations are accomplished almost instantaneously. The accompanying volume changes lead to disruption of ware containing significant amounts of quartz or cristoballite.

#### 3.26.7.2.2 Thermal expansion

The coefficient of thermal expansion of vitreous silica is very small (5.4×10<sup>−7</sup> over the range 0–1000 °C), about one-sixth that of porcelain. It is thus highly resistant to thermal shock.

**Figure 2** Polymorphism and dimensional changes in silica as a function of temperature.

### 3.26.7.2.3 Heat resistance

Being a glass, vitreous silica softens progressively as it approaches its melting point of 1713 °C. The maximum recommended working temperature is 1050 °C in an oxidizing atmosphere, though it may be taken to 1350 °C for short periods. Surface devitrification to cristoballite occurs above this temperature. This causes some loss of transparency, but chemical and mechanical durability are unaffected provided the temperature does not fall below the  $\beta$ - $\alpha$  inversion temperature (275 °C), which would lead to the initiation of cracks. It should be noted that devitrification is accelerated by traces of alkali-metal compounds, particularly potassium and lithium salts, sodium tungstate, and ammonium fluoride. Devitrification is also enhanced by water vapor and oxygen, but inhibited by neutral or reducing atmospheres.

### 3.26.7.2.4 Thermal conductivity

The thermal conductivity of fused silica is low ( $1.38 \text{ W m}^{-2} \text{ K}^{-1}$ ). The transparent form passes infrared radiation with little loss up to wavelengths of 3.5  $\mu\text{m}$ .

### 3.26.7.2.5 Electrical characteristics

The insulating properties of glass are excellent. At ordinary temperatures, the resistivity of the translucent form is  $10^{15} \Omega \text{ m}$ , and it is capable of withstanding high-frequency discharges at high voltages. See also [Table 1](#) for data on other physical properties and for comparison with other glasses.

### 3.26.7.3 Resistance to Chemical Attack

Most glasses suffer chemical attack and deterioration due to ion exchange of sodium ions to form a highly alkaline solution, which subsequently attacks the network. As network-modifying oxides are absent from fused silica, this mode of attack does not occur. Hence fused silica is highly resistant to most aqueous solutions, even aqua regia at elevated temperatures having no effect. Reagents that attack the network silica directly, such as strong alkalis and fluorides, cause serious damage and are therefore to be avoided.

#### 3.26.7.3.1 Boiling water and steam

There is limited reaction with water and steam at moderate temperatures and pressures. However, silica is slightly soluble up to around 6 ppm. However, at temperatures in the range 400–500 °C and pressures of the order of 3.5 MPa the solubility rises to 0.14% for the translucent form and 0.035% for the transparent.

#### 3.26.7.3.2 Fluorine, hydrofluoric acid, and alkaline solutions

Silica is susceptible to attack by all three reagents, the rate of corrosion increasing with temperature and concentration. Although 5% caustic soda solution can be contained in fused silica at room temperature, attack becomes significant at pH values greater than 9, as shown in [Figure 3](#).

**Figure 3** Effect of pH on the rate of silica extraction from vitreous silica powder at 80 °C. Reproduced from El-Shamy, T. M. M.; Douglas, R. W. *J. Am. Ceram. Soc.* **1967**, 50, 1–7.

The essential step in the dissolution reaction of silica is the breaking of a siloxane bond Si–O–Si. This bond, although strong, is polar, and may be represented as (Si<sup>δ+</sup>–O<sup>δ–</sup>). The excess positive charge associated with the silicon atom makes it susceptible to attack by nucleophilic reagents such as the hydroxide ion, which attaches itself to the silicon, rupturing the network at that point. The attack by HF on silica is thought to proceed by a similar mechanism in which there is simultaneous nucleophilic and electrophilic attack on the network silicon and oxygen atoms, respectively. It should be pointed out the H<sup>+</sup> ion cannot effect disruption of the siloxane bond without the simultaneous action of the F<sup>–</sup> ion. Consequently, sulfuric and nitric acids do not initiate attack even at temperatures up to 1000 °C.

Sodium fluoride also attacks silica, as do sodium metaphosphate and sodium polyphosphate, and to a lesser extent sodium carbonate and sodium cyanide. Attack is particularly vigorous for fused alkalis, alkali halides, and phosphates.

### 3.26.7.3.3 Basic oxides

As an acidic oxide, SiO<sub>2</sub> is resistant to attack by other acidic oxides, but has a tendency towards fluxing by basic oxides. An indication of the likelihood of reaction can be obtained by reference to the appropriate binary phase equilibrium diagram. The lowest temperature for liquid formation in silica oxide binary systems is shown below:

Oxide	Al <sub>2</sub> O <sub>3</sub>	BeO	CaO	MgO	ThO <sub>2</sub>	TiO <sub>2</sub>	ZrO <sub>2</sub>
Eutectic (°C)	1546	1670	1436	1543	1700	1540	1675

### 3.26.7.3.4 Metals

Silica is decomposed only by those metals that have a high thermodynamic affinity for oxygen. On this basis, molten sodium should be compatible with silica:

Although the equilibrium levels of the reaction products are very small, both can dissolve in liquid sodium; also sodium oxide can form compounds with silica. As a consequence, the reaction moves to the right, leading to further reduction of silica. Nevertheless, vitreous silica crucibles have been used successfully for containing molten antimony (850 °C), copper (1210 °C), gallium (1100 °C), germanium (1100 °C), lead (500 °C), and tin (900 °C).

In accordance with the free energy predictions, silica is readily attacked by molten aluminum, lithium, magnesium, and calcium.

### 3.26.7.4 Applications of Vitreous Silica

The high thermal and electrical resistance of vitreous silica, and its imperviousness to chemical attack, make it suitable for a wide range of applications. These include chemical and physical laboratory apparatus, tubes and muffles for gas and electric furnaces (including vacuum furnaces), pyrometers, insulators for high-frequency and high-tension electrical work, mercury-vapor and hydrogen-discharge lamps, high-vacuum apparatus, plants (complete or partial) for chemical and related industries, equipment for the manufacture of pure chemicals, tubes, chimneys and radiants for the gas- and electric-heating industries, component material in refractory and ceramic mixtures, etc.

It is used for pipes to carry hot gases and acids and in acid distillation units, condensing coils, S-bend coolers, hydrochloric acid cooling and absorption systems, nitrating pots, and cascade basin concentrators for sulfuric acid. The resistance of vitreous silica to most acids is also utilized in the manufacture of electric immersion heaters and plate heaters for acidic liquors in chemical processes and electroplating baths. Vitreous silica wool is used for filtration of acidic liquids and filtering hot gases. The resistance of vitreous silica to water and steam at normal temperatures and pressures makes it applicable in the production of pure water for the manufacture of highly purified chemicals. Because of its thermal properties, it is used for the construction of muffles of oval cross section used for the bright-annealing of metal strip and wires. Special products include transparent vitreosil components, which are ideal

for continuous measurement in corrosive atmospheres, and quick-immersion thermocouple protection sheaths for rapid temperature measurement.

### 3.26.8 Glass Ceramics

#### 3.26.8.1 Definition and Properties

Glass-ceramics are a family of materials that are polycrystalline in nature and are formed from the liquid or glassy state. A glass-ceramic article is made by the heat treatment of a vitreous body in two stages:

1. *Nucleation*: The glass is held at a temperature below its softening point for a period of minutes or hours to allow nuclei to develop.
2. *Crystallization*: The temperature of the nucleated glass is raised to just below the softening point when crystals form and grow around the nuclei.

Ideally the product is a fine-grained ceramic containing interlocking crystal grains of sizes ranging from less than 10 nm in transparent glass-ceramics to several micrometers, with a residual, usually small, glass content. The behavior of the material is largely determined by the choice of the crystalline phase; by suitable choice, a range of useful properties has been obtained.

As a class of materials, glass-ceramics have the following general characteristics:

1. Impervious, with moderate densities similar to those of glasses.
2. Improved fracture toughness compared with glass or ceramic materials.
3. Relatively high tensile strengths (a consequence of item 2).
4. Stiff, elastic (Hookean) limited-to-zero plasticity.
5. Considerable hardness and resistance to abrasion.

6. Chemical stability and resistance to corrosion.
7. Resistance to medium-high temperatures (higher temperatures than most glasses but lower than the refractory oxides) and low thermal conductivity.
8. Resistance to the passage of electrical current.

Special characteristics can be developed in individual materials depending on the cations present and their arrangement relative to each other and to the oxygen anions. The most important of these characteristics is low, medium, or high reversible thermal expansion. The properties of some commercially available glass-ceramics are summarized in [Table 4](#).

#### 3.26.8.2 Chemical Durability of Glass-Ceramics

While the chemical behavior of a glass-ceramic is strongly influenced by the chemical composition of the parent glass, several different crystalline compounds together with a residual glass phase are likely to be present. The relative resistances of these phases to attack by water or other reagents will determine the chemical stability. In general, a glass that exhibits poor chemical stability is unlikely to give rise to a glass-ceramic of high stability. To this extent, the factors that govern the stability of glass-ceramics can be equated to those that determine the chemical stability of glasses.

In most cases, glass-ceramics possess good chemical stability and certainly compare favorably in this respect with other ceramic materials. [Table 5](#) summarizes manufacturers' data for chemical attack on the materials listed in [Table 4](#).

Certain types of glass-ceramic have good resistance to attack by corrosive chemical reagents. Low-expansion glass-ceramics derived from lithium aluminosilicate glasses are only slightly inferior to

**Table 5** Chemical resistance data for the glass-ceramics listed in Table 4

	A	B	C	D	E
<i>Powder method</i>					
Water solubility (mg Na <sub>2</sub> O/mg sample)	0.29	0.8	128	0.1–0.3	0.12

borosilicate chemically resistant glass with regard to attack by strong acids and are somewhat more resistant to attack by alkaline solutions. Materials derived from magnesium aluminosilicate glass compositions are slightly less resistant to attack by strong acids and alkalis than are chemically resistant borosilicate glasses. Even at high temperatures, these types of glass-ceramic retain resistance to attack by corrosive gases. For certain applications, it is important that the glass-ceramic should be unaffected by contact with reducing gases at high temperatures. In such cases, the composition must not include any oxides such as lead, which are easily reduced to the metal.

### Glossary

**Adhesion (enamel-basis metal)** Amount of the force required to separate a coating from its basis metal and the area of the corresponding surface.

**Blister** Defect that appears as a localized bubble under the surface of the fired vitreous enamel.

**CIP** Cleaning in place – standard procedure in chemical plants to avoid or remove surface contaminations or settlements. Normally carried out after several production batches. pH and temperature are often just the

opposite of the regular production conditions.

**Cover coat** Vitreous enamel with specific chemical and/or esthetic properties as the final coat.

**Crazing** Defect resembling a network of fine hairline cracks in a coating.

**Fishscaling** Small half-moon shaped defects occurring in the vitreous enamelled surface. Can occur immediately on cooling or after some time has elapsed following firing. This defect originates from supersaturation of the substrate with hydrogen (acquired during firing), which explosively fractures the

enamel coating because of the pressure that has accumulated with time at the enamel–steel interface.

**Ground coat** Vitreous enamel, containing adherence-promoting agents and applied directly to the substrate to function as an intermediate bonding layer between the substrate and the cover coat.

**Scale** Oxide formed on the surface of a metal during heating at elevated temperatures.

**Spark test** High-voltage electrical test in which a spark is used to detect discontinuity in coating. Applied voltages can be as high as 20 kV.

**Technical enamel/vitreous enamel** Product formed by the heating of an inorganic mixture, to a temperature just high enough for fritting, or uniform fusion to occur. It is designed for application to metallic surfaces for protective, functional, and/or aesthetic purposes, and specifically will exhibit cubic thermal expansion of between 150 and  $450 \times 10^{-7} \text{ K}^{-1}$ , in the temperature range 20–100° C, the actual value varying specifically with the type of substrate and the field of application.

### 3.27.1 Introduction

While glass can provide many of the desirable features of an almost ideal inert material, manufacturing difficulties and safety considerations prevent its use in large-scale dimensions for chemical process equipment, and mechanical considerations would, in any

case, make it necessary to treat any such equipment with great care.

The high chemical resistance, and the nontoxic, nonflammable, nonflavorable, and thermal resistant properties of glass, can, however, be combined with the mechanical strength of metals by covering metal surfaces exposed to corrosive media with a layer of suitable glass. It thus becomes feasible to produce large-scale storage or transport tanks or to run large-scale reactors under high overpressures and extended temperature profiles. Reaction vessels, storage tanks, all-glass-lined pump smoke stacks, distillation columns, etc. can all be made of glass-lined equipment.

The principal advantage of glass linings is the increased size as well as the mechanical and thermal strength that are possible compared with all-glass equipment and the flexibility of operation with different chemicals compared with all-metal equipment. The increased heat transmission, in comparison with glass equipment, can also be an advantage.

The principal disadvantages are the loss of transparency and the potential vulnerability of the lining to mechanical damage unless sensible precautions are taken in handling, installation, and service. A variety of metals can be protected in this way, including copper, gold, stainless steel, titanium, and aluminum, but by far the most extensive use is for carbon steel based equipment.

The actual size of glass-lined equipment varies from 4 l autoclaves up to storage tanks that exceed a size of 120 000 l. The pressure regime under service can range from vacuum up to 25 bars in standard operation processes. Because of the often severe application properties run in glass-lined equipment, the sensor probes used to monitor production processes have to be made of glass or of glass-lined parts. These include acidity (pH) and potential (ORP-redox) probes, temperature sensors, conductivity measurements, and also glass-lined radar probes as well as oscillating sensing forks for fluid level measurement.

## 3.27.2 Manufacturing of Glass-Lined Steel Equipment

### 3.27.2.1 Glass Formulations

Glass frits used in vitreous enamels may contain as many as 20 components, though these may be classified in three functional categories: glass formers ( $\text{SiO}_2$  and  $\text{B}_2\text{O}_3$ , which constitute the random network of the glass), the dioxides ( $\text{ZrO}_2$ ,  $\text{CeO}_2$ , and  $\text{TiO}_2$ , which all enhance alkali resistance and are

also opacifiers), and the alkali and alkaline earths (which lower fusion temperature and increase the expansion coefficient). While high alkali (e.g., sodium, potassium) content lowers resistance to acid attack, adequate amounts are required to dissolve the oxides on the surface of the steel. Alkaline earth elements (e.g., calcium, barium), on the contrary, increases the chemical resistivity up to a certain extent. A kind of 'mixed alkali effect' additionally enhances the properties of the enamel by creating nanosized local stress inside the glass matrix thereby reducing the amount of easily dissolvable species. A relatively infusible ground-coat frit becomes supersaturated in iron oxide, which eventually crystallizes in the enamel, a defect known as 'copper heading.' Compromise is necessary, as too fluid a ground-coat results in over-rapid reaction and 'burning off,' precipitating the chipping of the enamel coating later on. Ground-coat frits contain much more boron oxide than the enamels used for the cover coat. Additions of alumina can be used to control viscosity, surface smoothness, and mechanical hardness of the glass.

Depending on the field of application, specific chemical, surface, and manufacturing properties of the enamel are required, resulting in compositions most appropriate for the area of the specific subject. This results in two different composition schemes 'A' and 'B' for technical enamels and enamels for domestic appliances respectively, which are schematically shown in the composition triangle in **Figure 1**. **Table 1** lists the oxides most often used for glass making. A high silica-to-boric oxide ratio composition is used for industrial enamels in reaction vessels and in hot water tanks where the higher firing temperature is required for improved chemical and thermal resistance.

**Figure 1** Area 'A' represents the chemical composition of technical enamels, 'B' shows the much wider area of enamels used for domestic appliances, such as cookware, burner cups, fridges, ovens, bath tubs, architectural panels, etc.

### 3.27.2.2 Glass Preparation

Most of the manufacturers of glass-lined equipment have their own glass formulations, although frit manufacturers also sell appropriate frits. In most cases, the chemical constitution has not been disclosed, but the more successful types are borosilicates containing high amounts of silicate (>55 wt%), aluminum, and alkaline earth oxides than do the typical heat-resistant borosilicates.

In formulations for ground coating the steel, the glass composition contains more cobalt and manganese oxide than do ordinary glasses to enable a better adhesion to the plain steel surface and to form a chemical bond between the metal and the glass. The thermal expansion coefficients of the glasses are of the order of  $(8-9) \times 10^{-6} \text{ K}^{-1}$  for this application, but vary for other metallic substrates. The disparity between these figures and the higher expansion coefficient of the steel, which is in the order of  $14 \times 10^{-6} \text{ K}^{-1}$ , is quite deliberate and results in the development of compressive stresses in the glass layer after processing (i.e., after cooling from the sintering temperature). The stress developed gives more resistance to thermal shock or external stresses than if the expansion coefficient of the glass and steel were accurately matched.

The raw materials required to produce the particular glass composition are thoroughly mixed and melted at temperatures above  $1300^\circ\text{C}$ . The melt is normally quenched directly into cold water, but often quenching is carried out using cooled copper-based rolling blades. While the directly quenched melts produce irregularly shaped, cracked particles, the rollers form disc-like shapes.

Both types of frits are ground in the same way, either dry to form powders or wet-milled with clay and quartz added to form a viscous slip. It can be applied to steel by spraying or dipping, depending on the shape, size, and design of the structure.

**Table 1** Oxides used in glass manufacture

Glass former	Glass modifier $R_2O$	Glass modifier $RO$	Glass former $RO_2, R_2O_3$	Adhesion promoter
$SiO_2$	$Li_2O$	$MgO$	$TiO_2$	$CaF_2$
$B_2O_3$	$Na_2O$	$CaO$	$ZrO_2$	$MnO_2$
	$K_2O$	$SrO$	$SnO_2$	$CoO$
		$BaO$	$Fe_2O_3$	$NiO$
		$ZnO$	$Al_2O_3$	

### 3.27.2.3 Metal Preparation

A low-carbon ( $<0.2\%$  C) steel is usually used in the manufacturing of chemical process reactors or storage tanks, distillation columns, and the like; the steel quality is defined in several standards,<sup>1–3</sup> which include also the minimum and maximum content of other constituents than that of iron, and stipulate surface standards prior to the lining process. For other parts of the reactor, such as nozzle parts, pipes, etc., specific requirements are defined in various EN standards.<sup>4,5</sup>

These requirements contain the maximum content and diffusivity of hydrogen, amount of slacks, and define test methods for estimating the propensity for defects such as fishscaling, blistering, crazing, scaling, and poor adhesion. Cast iron is frequently used in equipment such as valve bodies and pipe unions. It should be of good quality, close-grained gray iron, free from blow-holes, cavities, and porosity. Repair of such defects by filling is not permissible in the reactor field.

Conventional welding techniques are used in production and assembly of the steel body, but special precautions must be taken to ensure that the weld metal is of a similar composition to the base metal. Moisture-free electrodes must be used.<sup>6–8</sup> According to the assigned production place, the equipment has to fulfill different local requirements, which are all specified in technical rules.<sup>2</sup>

### 3.27.2.4 Certifications

This knowledge about industrial enamel and the glass lining process is the basis of the European glass lining industry. It is used to manufacture highly sophisticated products according to ISO 9001, APAVE, ASME, Druckgeräterichtlinie, China Code, etc., which are certified regularly by external audits of the manufacturers.

The design and dimensioning of a specific vessel results from customer requests and should be in accordance to the local laws and standards. **Table 2** lists some of them.

All these regulations define how a vessel has to be designed and also how the required quality has to be controlled. They assess criteria for welding and lay down instructions that define accompanying material tests to ascertain the overall quality of a vessel. All these instructions increase the amount of testing enormously, and make the production more costly,

**Table 2** List of technical rules to define good manufacturing procedures used for manufactured products related to chemical industry

<i>AD 2000 Merkblatt HP-0</i>	<i>ATEX 94/9/EG</i>	<i>DIN EN 729-2</i>
DGRL97/23/EG	ASME R	TRD 201
SVTI	ASME NB	CODAP
UIC	ASME U	DIN 6700-2
AQSIQ	DIN ISO 9001:2000	

but ensure a safe running of a chemical plant where they are applied to. In the end, they lead to the international reputation of equipment manufactured in Europe (**Table 3**).

Typically, a completed steel assembly is examined in detail by ultrasonic and X-ray detection to check for defects likely to impair serviceability. It is then often normalized above  $860^{\circ}\text{C}$  to relieve stresses arising from fabrication and to reduce hydrogen content. The heat treatment also has the advantage of burning off organic contamination and carbon residues localized near the steel surface. After cooling, the vessel is sand-blasted either with silica grit or steel shot to remove the scale formed during the normalization procedure and promote mechanical keying of the glass ground-layer to be applied (by roughening the surface). Degreasing and chemical descaling is no longer used for large-scale equipment because of the risk of hydrogen uptake and consequent fishscaling and also for environmental restrictions.

Important points in vessel design are

1. The metal thickness should be as uniform as possible throughout, avoiding heavy bosses, lucks, or brackets.
2. Sharp edges must be avoided under all circumstances, the minimum radius recommended for all curved surfaces is  $\sim 8\text{ mm}$ , at complex-shaped parts, and with smaller dimensions, radii can be as small as  $3\text{ mm}$ . The risk of sudden shaling increases as the radius decreased. Therefore, for such parts, thickness limitations are defined.
3. The risk of distortion on firing is greater if the design includes numerous apertures in the vessel or its cover.
4. The minimum metal thickness must take into consideration that the mechanical strength of steel decreases sharply during heating. Several standards<sup>9</sup> define maximum tolerances for deviations from the original design.

**Table 3** List of technical standards which define technical requirements and material flow and documentation procedures for manufactured products related to chemical industry

EN 14483-1 to 5	Defines physical and chemical properties of glass coatings. Describes testing devices and procedures
EN 14430	Defines spark testing devices and technical spec for glass linings
EN 15159-1 to 2	Technical delivery conditions, min spec of glass linings and vessels defined
CODAP	French standards, include welding procedures, heat treatment and material flow until delivery of glass-lined devices
Swiss standard	Swiss standards, include welding procedures, heat treatment and material flow until delivery of glass-lined devices

### 3.27.2.5 Lining Process

The first coat consists of a ground-coat, which is sprayed as the first layer in the form of a wet slip. After drying, it is normally fired at temperatures above 900 °C. The alternative, directly dusting hot parts with dry powder, has diminished completely. After inspection, either a second ground-coat or several cover coats are applied directly. Each coating allows a buildup of ~0.3–0.5 mm of glass, which means that an average of 4–6 coats are required to build up a desired glass thickness of 1.5–2 mm.

Each coat is dried thoroughly and is fired according to a firing program, especially designed for each part. Cover coats are fired between 780 and 850 °C, depending on the size of the part, glass type, and coat number. To avoid thermal-induced stresses within the glass lining, slow cooling is most appropriate for a high standard of quality. Inadequate cooling rates lead to a number of severe defects,<sup>10</sup> which are not accepted by customers.

To avoid any kind of defect, for example, blisters, bubbles, scale, etc., visual inspection and spark testing at 20 kV after each coat reveals the integrity of the coating. To ensure pore-free quality, small defects are ground and refilled with cover coat slip, blisters are ground down to the steel, and, by using special patch grounds in combination with cover coats slips locally, a homogeneous and sound layer of glass can be built up again.

## 3.27.3 Properties of Glass on Steel

### 3.27.3.1 Mechanical Properties

With a properly formulated glass and correct firing, the lining withstands stresses up to the elastic limit of steel without breaking. Impacts sufficiently severe to dent steel will probably cause fractures in the lining. The hardness and abrasion-resistance of the lining exceeds the properties of all-glass equipment, and a smooth and easily cleaned surface is

produced during firing. The combined effect of mechanical keying of the glass to the metal and the chemical bonding developed between glass and steel results in very high adhesive strength.<sup>11</sup> Thus, at room temperature, the typical bond strength of glass to steel can be greater than 100 MPa, the fracture toughness is  $\sim 70 \text{ MPa m}^{-1/2}$  and compressive strength reaches 800 MPa.

### 3.27.3.2 Thermal Properties

The thermal shock resistance of glass-lined equipment, that is, the safe limit of the temperature difference between the glass surface of the vessel and any charge introduced varies to some extent according to general operation conditions. Minimum values are defined in the EN standard 15159-2. To fulfill the requirements of chemically inert industrial enamel, a value of at least 190 °C is required. Modern industrial vitreous enamels are much better and can withstand even sudden temperature changes of 220 °C, on defined standardized test plates.

For reactors, a maximum temperature difference of 140 °C, according to EN 15159-3, is allowed. This value is very close to the thermal shock borderline of steel, where a sudden temperature difference leads to plastic deformation of the steel substrate, causing severe cracking in the glass.

Plant operation temperatures vary nowadays from –150 up to 280 °C, with the maximum operating temperature limited by the corrosivity of the liquid in contact with the enamel. The heat transfer coefficient for heating in glass-lined equipment is of the order of  $400 \text{ W m}^{-2} \text{ K}^{-1}$  but can be increased by agitation. For cooling, corresponding figures would be<sup>12</sup>  $280 \text{ W m}^{-2} \text{ K}^{-1}$ . The numerical values depend on the thickness of the glass coating, increasing with decreasing glass thickness, and the figures quoted represent the behavior of an average coating of 1.4 mm in thickness.

### 3.27.3.3 Chemical Properties

The general pattern of chemical durability of glass linings is higher than for all-glass equipment. Water absorption is negligible, chemical resistance is very high to all acids except hydrofluoric acid and at high temperatures and concentrations of phosphoric acid. Attack by water is measurable only with great difficulty, leading to deviations caused largely by quality of the used water. Almost all organic solvents produce no measurable effect, and strong alkaline solutions (e.g., 20 wt% NaOH) are satisfactorily handled up to at least 60 °C; above that temperature, there might be appreciable reaction. For most types of chemicals, corrosion of the enamel can be assessed by measuring the loss in thickness either in weight per unit area and time or by directly calculating thickness loss when exposed to the liquid.<sup>13</sup>

Conditions in service vary widely. Many cold liquids (milk, ketchup, and beverages) have little corrosive action, and the chosen glass lining need not be very acid-resistant. By contrast, very often base chemicals are produced, which need high temperatures and strong inorganic acids often under high pressure for processing; glasses, therefore, have to be extremely chemically resistant. Further needs are high durability against leaching effects. Thus, the modern semiconductor industry asks for impurity concentrations of their products (pigments, LCD crystals) at the ppb level. Only a few of the modern industrial enamels fulfill these exacting requirements. In the life-science industry, normally acid-based reactions are carried

out, but cleaning in place (CIP) often requires the use of strong alkaline solutions at high temperatures, so the resistance to caustic attack needs to be much higher than in the past.

### 3.27.3.4 Testing Methods

Investigations recently carried out on the leaching effects during corrosion tests showed that the time used for running the tests has a significant influence on the achieved results. Excessive time periods lead to an increase in dissolved glass constituents, which then again further hinder corrosion of the glass. This inhibition effect, described by the mass balance equation, is an ongoing process of glass corrosion. New EN standards with drastically increased concentrations of corrosive media and reduced reaction times especially for alkaline testing have overcome these effects and now lead to better and reproducible data.<sup>14</sup> The values hold for both immersion and vapor-phased conditions, depending on the media used (Table 4).

The effect of temperature on alkaline corrosion is illustrated by data from Pfadler.<sup>11</sup> There are various glass compositions in service, and it is important to ensure that the lining is appropriate for the particular process to be carried out. An example of the behavior of two different technical enamels compared with borosilicate and lime glass is shown in Table 5. This table gives some resistance data with regard to typical acids and alkalis, all data measured according to EN 14483-1-5.<sup>13,14</sup>

**Table 4** The durability of several materials against chemical attack

Material	Acidic solutions			Alkaline solutions		
	HCl (20%)	H <sub>2</sub> SO <sub>4</sub> (60%)	HNO <sub>3</sub> (25%)	NaOH (5%)	Na <sub>2</sub> CO <sub>3</sub> (10%)	NH <sub>3</sub> (1%)
WWG	0.039 (108 °C)	0.1 (160 °C)	0.1 (135 °C)	0.51 (80 °C)	0.10 (56 °C)	0.1 (82 °C)
PPG	0.046 (108 °C)	0.1 (160 °C)	0.1 (135 °C)	0.32 (80 °C)	0.10 (63 °C)	0.1 (92 °C)

### 3.27.3.5 Surface Properties

For several applications, the smoothness of the glass surface is the most important factor, making glass more attractive than stainless steel vessels, for example. Polymer producers ask for very smooth surfaces with nonstick behavior, thereby improving the cleanability of the enameled reactor walls compared with stainless steel ones. Even if the thermal properties of a glass-lined reactor are worse than those of stainless steel, because of higher sticking rates of polymer particles on stainless steel, glass-lined reactors achieve at least similar performance rates during service.

### 3.27.3.6 Enamel Behavior in Service

Enamels, although resistant to many alkalis, are not necessarily completely resistant. Thus, weight loss from enameled iron test pieces has been related to resistance to detergent attacks, but field assessment of the effect of alkaline materials upon enamel does not always agree with accelerated laboratory tests. In such a case, the fitting of a glass-lined test piece into the vessel is required. The production test can last for several weeks, allowing a realistic calculation of the durability of the glass. Often, large differences between enamels occur depending on their chemical composition. Often, also minor changes in the production process have a drastic influence and increase on the performance of a glass lining. As an example, addition of caustic soda above 80 °C is often used to neutralize a product.

If the addition is done solely through a nozzle at the upper bottom, no fast mixing between the two liquids occurs, which would corrode the glass within a distinct zone near the edge of the liquid level. By using a dip pipe for the addition of the caustic soda,

complete mixing and dilution occurs immediately, drastically reducing the chemical attack and also improving the performance of the process.

### 3.27.3.7 General Aspects of Glass Enamel Corrosion

Evidence (about the interaction of liquids with glass surfaces) has come from the results of research work in developing corrosion-resistant glass compositions and there is now better understanding of the mode of chemical attack on glass. Reaction on the surface occurs through ion exchange, dissolution, and absorption. Signs of these reactions are a dimming of gloss, thin film interference colors, and surface-roughening on general degradation. In the beginning, the corrosion becomes apparent as a loss of gloss, but there is no direct correlation between gloss and chemical degradation by ongoing attack. Continued penetration of the glass structure by some ions could lead to its decomposition. The thickness of the ion-exchanged surface layer is related to the durability of the glass and initial reactions are rapid.<sup>18,19</sup> An intermediate phase is formed whose structure, thickness, and durability depends on the glass composition as well as the temperature and pH of the attacking/reacting liquid.<sup>20</sup>

The borosilicate glasses on coated steel contain silica and alkali metal oxides and the reactions can be considered as involving silicate networks. Attacks begin as an interaction between silicate lattice ions and protons from the liquid with the consequent leaching of monovalent and divalent ions.

### 3.27.3.8 Attack by Water

No enamel or glass is thermodynamically stable against attack by water. The durability is caused by

the diffusivity of alkali ions inside the silica network. This can generally be described by a diffusion kinetics and thus follows a  $\sqrt{t}$ -relationship. Initially, there is the replacement of an alkali ion in the glass by a proton (H) from the water,

The released hydroxyl ion shifts the pH of the solution and interacts with the siloxane bond in the vitreous network

This open oxygen interacts with a water molecule to form dissolved silicic acid

The resulting hydroxyl ion is available for further reaction in reaction [2]. As the hydrogen ions replace alkali (R) ions, a surface film forms, which has properties different from the solid glass. This film swells, acting as a barrier to further diffusion of ions into and out of the bulk material, thus inhibiting further attack. If this layer dries out, the thin films produce characteristic, iridescent interference colors. Depending on the chemical durability of the glass, the mechanism of attack varies. Highly chemical-resistant enamels withstand the  $\text{OH}^-$  attack, and corrosion is mainly caused by ion exchange and proton interaction. This leads to the general equation

### 3.27.3.9 Attack by Alkaline Solutions

With the migration of alkali ions ( $\text{R}^+$ ) into the leachant, attack is no longer solely by water. If  $\text{R}^+$  is sodium, the attack on the glass is

Alkaline ions in solution increase the pH with two consequences. The rate of silica extraction increases with rise in pH value above 8–9 and the rate of alkali exchange is reduced. However, as the higher alkalinity favors dissolution of silica, further alkali is released by the lattice. The quantity of alkali extracted can be used as a measure of the resistance of the glass to attack.

### 3.27.3.10 Attack by Acid

#### 3.27.3.10.1 Mineral acids

The mode of attack with mineral acids is similar to that by water, namely at the site of siloxane bond  $-\text{Si}-\text{O}-\text{Si}-$ . Hydrochloric, sulfuric, and nitric acids all attack through similar mechanisms. Phosphoric acid, when almost water-free, is no more corrosive than the other mineral acids. However, diluted phosphoric acid forms polyanionic networks that are good complexing agents and increase the leaching of monovalent and divalent cations from the vitreous network (via the formation of alkaline and alkaline earth silicyl phosphates).

#### 3.27.3.10.2 Organic acids

Some glasses are more prone to attack by organic acids than by other acids with a lower pH value. These acids form complex ions in solution, which increase the glass solubility. Many vitreous enamels contain larger divalent cations in their network, specifically Ca, Sr, and Ba ions reduce ion diffusivity in the lining.

### 3.27.3.11 Further Possibilities of Corrosive Attack on Glass

#### 3.27.3.11.1 Attack by complex formation

Chelating agents sequester polyvalent cations and, if present in a corrosive liquid, can increase the rate of attack on the glass. The cations  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Al}^{3+}$ ,  $\text{Zr}^{4+}$ , and  $\text{Ti}^{4+}$  are known to stabilize the siliceous surface film and so aid corrosion resistance, but in the presence of say, ethylenediaminetetraacetic acid (EDTA), with which these ions interact, this protective action is increasingly nullified as the ions are removed from the silicate surface. Complexes are formed between  $\text{Si}^{4+}$  and some organic acids, notably gallic acid and tannic acid.

#### 3.27.3.11.2 Attack by fluorides

All silicates are severely attacked by hydrofluoric acid and its constituents with  $\text{F}^-$  ion acting as a catalyst. Only the form of the silica network influences to some extent the reaction rate.

Although neutralization reduces the rate of fluoride attack, no inhibition of this process is so far known.

### 3.27.3.12 Inhibition of Corrosion Attack

The reaction routes of chemical attack aforementioned also open the possibility for inhibiting the attack on glass by altering the chemical equilibrium to favor the reactant (glass) side of the equations. Thus, appropriate chemical additions can reduce the glass dissolution rate considerably. This holds especially for attack of protons on glass where the addition of dissolved  $\text{SiO}_2$  into the process fluid shifts the equilibrium constant towards a higher stability of the vitreous glass matrix. Formally, reaction [8] is used to calculate the amount of dissolved  $\text{SiO}_2$  necessary to stabilize the lining.

Equilibrium is achieved when the dissolution concentration of the main constituent  $\text{SiO}_2$  reaches saturation level.  $[\text{H}_2\text{SiO}_3]_{\text{diss}}$  describes the amount of dissolved  $\text{SiO}_2$ ,  $[\text{Na}_2\text{SiO}_3]_{\text{glass}}$  stands for the glass matrix containing alkaline ions.

$$K = \frac{[\text{H}_2\text{SiO}_3]_{\text{diss}} [\text{NaOH}]^2}{[\text{Na}_2\text{SiO}_3]_{\text{glass}} [\text{H}_2\text{O}^2]} \quad [9]$$

The addition of a small amount (normally 100–300 ppm) of  $\text{SiO}_2$ , according to eqn [9], shifts the equilibrium towards the reactant side and therefore hinders glass corrosion.

### 3.27.3.13 Effect of Leaching – Temperature Dependence

The quantity of alkali extracted from a glass matrix in a fixed time increases with increasing temperature. Depending on the composition of the glass coating and the alkali present (ions of different size behave differently) the amount leached approximately doubles for each  $10^\circ\text{C}$  rise in temperature. This temperature dependence can be expressed by the equation (Arrhenius):

$$A = B \exp(-\Delta E/RT) \quad [10]$$

where  $A$  is the specific reaction rate changing with temperature,  $B$  is a constant,  $R$  is the gas constant,  $T$  is

the absolute temperature, and  $\Delta E$  the activation energy for the process of alkali removal from the glass. Alkali extraction is always associated with changes in pH and such changes depend on the quantities of alkali and silica released. For details, see the mechanism of water attack. Where glass linings are exposed to water or steam at temperatures above  $160^\circ\text{C}$  and/or at extreme pH values, the plant manufacturers should be consulted.

## 3.27.4 Damage Monitoring and Analysis

### 3.27.4.1 In Situ Sensing Technology

Glass damage or corrosion may be monitored by applying a low voltage to the coated metallic substrate and recording the resulting current, which must necessarily flow from any damaged parts of the coating that significantly expose the metallic substrate. Provided that a history of the plant process and the type of insulating material used on the equipment installed is known, this can provide a record of the percentage of damaged (or unharmed) coating. Three methods are used to monitor glass defects, which have no need of additional installed test samples: Low DC voltage method that measures the overall ohmic resistance of a vessel<sup>21</sup>; electrochemical noise analysis that records and analyses the frequency-dependant noise spectrum of a vessel<sup>22</sup>; potentiometric decomposition analysis that measures the electrochemical potential of steel in a conductive solution.<sup>23,24</sup>

All three methods require at least some electrical conductivity of the solution, and all use the vessel (i.e., metallic substrate) as one of the working electrodes.

1. Simple voltage–current measurements are restricted by the specific conductivity of the liquid (must be high enough – works normally in all water-based liquids) and all installed parts demonstrate insulating behavior. A defect is recorded if the current exceeds a previously defined level. The method can lead to a large number of false alarms and, as such, is often not so useful (with the monitoring equipment being shut down).

2. Electrochemical noise analysis records the frequency spectrum (from mHz up to a few kHz) on the sample and looks for deviations from historic records that can indicate ongoing corrosion. However, the noise spectrum can often change drastically depending on the process conditions where this does not imply defect formation. Interpretation is thus quite difficult and automatic computation does not work well. Often the onset of corrosion is unseen or misinterpreted.
3. The potentiometric decomposition analysis overcomes these limitations. Recent developments allow the monitoring of glass defects also if metal parts such as nickel-based inlet tubes or graphite-filled polytetrafluorethylene (PTFE) linings or metal-based distillation columns are used. The method is based on the EMF build-up by an electrochemical cell. It makes use of the specific electrochemical potential of each element which is unique among all types of solutions and compositions, pH values, or temperatures.

The potentiometric method is based on the definition of electrochemical potentials, where the zero point is defined as the standard hydrogen electrode of potential equal to 0 V at 25 °C at 1 bar pressure of hydrogen and a solution that is 1 molar in proton concentration. Noble metals produce positive potentials, base metals negative ones.

Advantages of the method include ease of adjustment to a computer-based monitoring system, short time cycles (within minutes), and relative lack of dependence on changes in pH, temperature, or composition of the solutions.

### 3.27.4.2 Repairs to Enamel Damage

Repair cements are quite satisfactory and economical for mild chemical service over lengthy periods. For severe chemical service, enameled areas up to 120 mm in diameter can be repaired by specialists with tantalum plugs, discs, and PTFE gaskets. These materials have a similar chemical resistance to that of glass. Larger areas of damage or corrosion need special glass-lined plates (covers) fixed with several studs and cement.

Complete reenameling of equipment is feasible, but is often accompanied by a microstructural changes in the metal, and for this reason, it is limited to 4–5 times. With each reenameling distortion becomes larger and the process may consequently be uneconomical. For this reason, a complete inspection of a vessel is required to allow a decision as to whether reenameling or a new vessel is the more economical alternative.

### 3.27.4.3 Recent Developments

The traditional method of producing glass-lined vessels involves stages of annealing, degreasing, shot blasting, acid pickling, followed by application of up to two ground coats and five cover coats, each with a separate firing. Tighter legislation and higher energy costs have led to the development of processes in which one or more of these stages may be omitted. These advances are achieved through greater understanding and control of glass composition, and by adopting more sophisticated powder-handling techniques. This includes statistical methods of running a vessel mixture of various shapes, dimensions, and different coats-to-finish in one furnace run.

The more demanding the requirements of customers using enameled vessels for their production, the finer the resolution of analytical instruments being developed and the lower the permitted amounts of dissolved glass constituents in the products. These implications are requested especially by life-science companies and the semiconductor industry, as they call for decreases in the allowed level of leached impurities to almost 1 ppb. Mainly, impurity levels of transition metal oxides reduce the yield of product drastically, making it impossible to produce them in the qualities demanded. Typical examples are enantioselective oxidation reactions of proteins, manufacturing of LCD crystals, and photoresistant chemicals for the chip industry. This has led to the development of new enamels that consists only of biologically nontoxic metal oxides and that therefore remove CoO, NiO, MnO, Fe<sub>2</sub>O<sub>3</sub>, SnO<sub>2</sub>, ZnO, Cr<sub>2</sub>O<sub>3</sub>, SrO, and BaO from the glass compositions.

### Glossary

**Frit** A complex of oxides of boron and silicon with alkali and transition metals forming a glass that is suitable for fusing onto a metal, thus forming a vitreous enamel coating.

### 3.28.1 Nature of Vitreous Enamels

A vitreous enamel coating is, as the name implies, a coating of a glassy substance which has been fused onto the basis metal to give a tightly adherent hard finish, resistant to many abrasive and corrosive materials. The purpose of modern vitreous enamels is twofold, that is, to confer corrosion protection to the metal substrate and at the same time provide permanent color, gloss, and other aesthetic values.

Most of the corrosion resistance, and indeed other properties of the finish, are determined by the composition of the vitreous enameller's raw material *frit*, although other factors can influence them to a minor degree. Frit, for application to sheet and cast iron, is essentially a complex alkali-metal alumino borosilicate and is prepared by smelting together an intimate

mixture of refractory materials such as silica, titania, feldspar, china clay, etc. at temperatures between 1100 and 1450°C with fluxes exemplified by borax, sodium silicofluoride and nitrates and carbonates of lithium, sodium and potassium. Smelting continues until all the solid matter has inter-reacted to form a molten mass; but unlike true glass, this liquid does contain a degree of bubbles. At this stage the melt is quenched rapidly by either pouring it into water or between water-cooled steel rollers to form 'frit' or 'flake.'

Frit may be milled dry or wet. The long established dry process is used for cast iron baths and for chemical plants. Where possible the preferred process for vitreous enamel application today is dry electrostatic. The frit is milled with low level additions of refractory and/or inorganic pigments together with typically 0.3–0.4% of a silicone. The silicone imparts the required electrical characteristics to the ground frit to enable efficient application of the powder to the metal substrate. This is achieved in cylinders using balls of porcelain, steatite or denser alumina, or with pebbles of flint, to produce a fine powder of predetermined size.

In the more common wet process, frit is milled with water, colloidal clay, opacifier, coloring oxide, refractory and various electrolytes in a ball mill to a closely controlled fineness or coarseness.

The standard method of cleaning cast iron for enameling is by grit or shot blasting, which may be preceded by an annealing operation.

### 3.28.2.2 Steel

Two general types of sheet steel are in current use, *viz.* cold-rolled mild steel and decarburized steel. A typical analysis for cold-rolled steel is 0.1% C, 0.5% Mn, and 0.04% S. It can be obtained in regular, deep drawing or extra-deep drawing grades. This type of steel is normally used with a ground coat including cobalt and nickel, as shown in [Table 1](#).

Decarburized steel is mild steel that has undergone heat treatment in a controlled atmosphere to reduce carbon content to about 0.005%. White or coloured enamel can then be applied directly to this type of steel without the need for a ground coat layer.

Sheet steel is normally prepared for application of enamel by a sequence of operations including thorough degreasing, acid pickling, and neutralization. A nickel

[illegible]

Frit	100	
Water	35–40	
Titania	1	
Clay	2.5	Grind to fineness of 1 g residue on 200 mesh sieve (50ml sample)
Bentonite	0.3	
Sodium nitrite	0.05	
Potassium carbonate	0.1	

dip stage is often included to deposit a thin, porous layer of nickel applied at about  $1\text{gm}^{-2}$ , especially when the conventional ground coat is not used.

### 3.28.2.3 Enamel Bonding

For effective performance, the enamel must be firmly bonded to the underlying metal and this bond must persist during use. The bond is formed by the molten enamel flowing into 'pits' in the metal, that is, mechanical adhesion, and by solution of the metal in the glass, that is, chemical adhesion. The coefficient of thermal expansion of the enamel in relation to the cast iron or sheet steel and enamel setting temperature determines the stress set up in the coating. As enamel, like glass, is strongest under compression, its thermal expansion should be slightly less than the metal.

### 3.28.2.4 Enamel Application and Fusion

Vitreous enamel is normally applied to the prepared metal or over a ground coat by spraying or dipping. Alternative wet techniques are used, of which the most common has been electrostatic wet spraying. Electrophoretic deposition from slurry has been found to be highly suitable for some components.

On sheet iron, a ground coat including cobalt and nickel, is generally used, but for mass production (e.g., cookers) use of decarbonized steel and direct application of colors is more common. This involves more complex steel pretreatment.

After drying the applied slurry, the enamel is fused onto sheet steel at about  $800\text{--}850^\circ\text{C}$  for about 4–5 min. For cast iron, a longer time and lower temperature are normal.

The old dry process enameling of cast iron (baths etc.) is no longer widely used. The method consisted of sieving finely powdered frit onto preheated casting and inserting it back into a furnace at about  $900^\circ\text{C}$  to produce the smooth finish.

In recent years increasing use has been made of the electrostatic application of a dry powder spray by many manufacturers, who require a limited range of colors. Dry electrostatic finishes are fused at temperatures in the same range as conventional ones.

## 3.28.3 Properties of Enamel Coatings Affecting Corrosion

### 3.28.3.1 Mechanical Properties

This group includes surface hardness, that is, scratch and abrasion resistance, adhesion and resistance to chipping, crazing, and impact. All these and other

properties depend upon adhesion between the vitreous enamel layer and the metal being good and remaining so.

There is no single test that will give a quantitative assessment of adhesion; all those which have been proposed cause destruction of the test plan. It has already been stated that this property is dependent upon mechanical and chemical bonds between enamel and metal. One must, however, also consider stresses set up at the interface and within the glass itself during cooling after fusion or after a delay.

The coefficient of thermal expansion is primarily determined by frit composition, although mill additions can have a minor influence. As a general rule, superior acid and thermal shock resistance are obtained with low expansion enamel, and the skill of the frit manufacturer is in obtaining good resistance and maintaining a sufficiently high expansion to prevent distortion of the component (pressing or casting). Several workers have produced a set of factors for expansion in relation to the enamel oxides that constitute the frit, which provides a guide to the frit producer. However, as these factors are derived from a study of relatively simple glasses smelted to homogeneity, it must be emphasized that they are only a guide. The effect of substituting certain oxides for others in standard titanium superopaque enamel is given in [Table 2](#). The use of a nickel dip improves adhesion by minimizing iron oxide formation, but it should be noted that some iron oxide formation is necessary to produce enamel/metal adhesion. In the most common methods of testing for adherence to sheet iron, the coated metal is distorted by bending, twisting, or impacting under a falling weight. In the worst cases the enamel is removed leaving the metal bright and shiny, but in all others a dark-colored coating remains with slivers of fractured enamel adhering to a greater or lesser degree. With cast

**Table 2** Effect of frit ingredients on enamel expansion

<i>Constituent varied</i>	<i>Expansion change</i>
Increase alkali metal	Increase
Replace $\text{Na}_2\text{O}$ by $\text{Li}_2\text{O}$	Increase
Replace $\text{Na}_2\text{O}$ by $\text{K}_2\text{O}$	Decrease
Increase fluorine	Decrease
Increase $\text{B}_2\text{O}_3$	Decrease
Replace $\text{SiO}_2$ by $\text{TiO}_2$	Increase
Increase $\text{TiO}_2$	Slight increase
Replace $\text{SiO}_2$ by $\text{Al}_2\text{O}_3$	Slight increase
Introduce $\text{P}_2\text{O}_5$	Slight increase
Introduce $\text{BaO}$	Increase
Increase $\text{SiO}_2$	Decrease

iron enameling it is not possible to distort the metal and in this case an assessment of adhesion is obtained by dropping a weight on to the enamel surface and examining for fractures. Erroneous results can be obtained in that often thicker enamel coatings appear to be better bonded and resistant to impact, whereas in fact the converse is true. Provided the bond is adequate, this test really gives an indication of the strength of the enamel itself.

According to Andrews<sup>1</sup> a typical sheet iron ground coat has a tensile strength of about 10 kg mm<sup>-2</sup>. In small cross-sections, however, the tensile strength of glass is improved and fine threads, for example, as in glass fiber, are quite strong. Enamels under compression are 15–20 times stronger than an equal thickness under tension.

The hardness of an enamel surface is an important property for such items as enameled sink units, domestic appliances, and washing machine tubs which have to withstand abrasive action of buttons, etc. On Moh's scale, most enamels have a hardness of up to 6 (orthoclase). There are two types of hardness of importance to users of enamel, *viz.* surface and subsurface. The former is more important for domestic uses when one considers the scratching action of cutlery, pans, etc. whereas subsurface hardness is the prime factor in prolonging the life of enameled scoops, buckets, etc. in such applications as elevators or conveyors of coal and other minerals.

Of the several methods of measuring this property, those specified by the Porcelain Enamel Institute and the Institute of Vitreous Enamellers are the best known and most reliable. Both consist of abrading a weighed enamel panel with standard silica or other abrasive suspended in water and kept moving on an oscillating table with stainless steel balls. The loss in weight is measured periodically and a graph of time versus weight loss indicates both the surface and subsurface abrasion resistance. Pedder<sup>2</sup> has quoted relative weight loss figures for different types of enamel. They are shown in Table 3.

Fine bubbles uniformly distributed throughout the coat improve elasticity and thus mill additions and under and over firing influence this property. The greatest effect on elasticity is enamel thickness and most developments are aimed at obtaining a satisfactory finish with minimum thickness.

### 3.28.3.2 Thermal Properties

These properties are made use of in many applications ranging from domestic cookers to linings which

**Table 3** Comparison of abrasion resistance of different enamels<sup>a</sup>

<i>Types of enamel</i>	<i>Average loss in weight (g)<sup>b</sup></i>
Acid resisting titania based	$56 \times 10^{-4}$
Acid resisting non-titania	$342 \times 10^{-4}$
Antimony white cover coat	$582 \times 10^{-4}$
High refractory enamel	$129 \times 10^{-4}$
Plate glass	$70 \times 10^{-4}$

<sup>a</sup>Data from Pedder.<sup>2</sup>

<sup>b</sup>Overall figure for tests under standardized conditions for each grade of enamel.

must withstand heat from jet engines. There is simple heat resistance, that is, the ability of the enamel to protect the underlying metal from prolonged heat and also thermal shock resistance, which is the ability to resist sudden changes in temperature without failure occurring in the coating. These thermal properties depend upon the relative coefficient of thermal expansion of enamel and metal, enamel setting point, adhesion, enamel thickness, and geometry of the shape to which the finish is applied.

It is obvious that adhesion must be good in order to prevent rupture at the enamel/metal interface during heating and cooling. Thick coatings are liable to spall when subjected to thermal change due to the differential strain set up within the enamel layer itself, caused by poor heat conductivity of the glass. Thus again thin coatings are desirable.

Compressive forces on enamel applied to a convex surface are less than when a concave surface is coated, and it is therefore apparent that the sharper the radius of the metal, the weaker the enamel applied to it will be. This fact is also relevant to mechanical damage.

Thermal shock resistance is important for gas cookers, pan supports and hotplates where spillage is liable to occur; but in oven interiors heat resistance is more relevant.

The softening point of conventional cast and sheet iron enamels is about 500°C, but special compositions are obtainable, which operate successfully at 600°C. Other more specialized enamels withstand service conditions ranging from being in excess of dull red heat, for example, as obtained in fire backs, to those capable of enduring short exposure to temperatures of around 1000°C, for example, in jet tubes, after burners, etc.

### 3.28.3.3 Chemical Resistance

That examples of glass and glazes manufactured many centuries ago still exist is an indication of the

good resistance of such ceramics to abrasion, acids, alkalis, atmosphere, etc.

In this section, chemical resistance will be divided into three parts, *viz.* acid, alkali (including detergents), and water (including atmosphere). Normally enamel is formulated to withstand one of the corrosive agents more specifically than another, although vitreous enamel as a general finish has good 'all round' resistance, with few exceptions such as hydrofluoric acid and fused or hot concentrated solutions of caustic soda or potash.

### 3.28.3.3.1 Acid resistance

This property is best appreciated when the glass structure is understood. Most enamel frits are complex alkali metal borosilicates and can be visualized as a network of  $\text{SiO}_4$  tetrahedra and  $\text{BO}_3$  triangular configurations containing alkali metals such as lithium, sodium and potassium or alkaline earth metals, especially calcium and barium, in the network interstices.

Fused silica may be regarded as the ultimate from the acid resistance aspect but because of its high softening point and low thermal expansion, it cannot be applied to a metal in the usual manner. Rupturing or distorting this almost regular  $\text{SiO}_4$  lattice makes the structure more fluid. Thus to reduce its softening point  $\text{B}_2\text{O}_3$  is introduced whereby some of the Si–O bonds are broken and an irregular network is formed. Further distortion of the network is obtained by introducing alkali and alkaline earth metals into the lattice. If fluorine is included in the frit, more bonds are broken; in this case an oxygen atom (–O–) linking two silicon or boron atoms is replaced by a fluorine atom (F–) – which, being monovalent, cannot join two Si or B atoms and hence causes bond rupture. A study of relevant phase diagrams and eutectics proves useful in formulating low firing enamels.

Thus all frit ingredients act as either network formers or modifiers and with the principal exception of silica, titania, and zirconia, all cause diminution in acid resistance. The reacting acid causes an exchange between metal ions in the network modifier of the glass and hydrogen ions from the acid. This naturally occurs at the enamel surface, but as the etching or

leaching reaction proceeds, a resulting thin layer of silica-rich material inhibits further reaction. Thus acid attack is dependent upon enamel composition and pH, with time and temperature playing a part. Sodium oxide and boric acid are both leached out by acid attack, and it has been found that the  $\text{Na}_2\text{O}/\text{B}_2\text{O}_3$  ratio is constant for any enamel and is dependent upon enamel composition.

An increase in titania content of the frit acts in a similar way to increasing silica in enhancing acid resistance with the added advantage that the coefficient of expansion is also raised slightly and the glass viscosity is not increased as much as by the equivalent  $\text{SiO}_2$  increment. This only applies to the titania remaining in solution in the glass and does not necessarily hold when the frit is supersaturated with  $\text{TiO}_2$ , which occurs with the modern opaque sheet iron covercoats when some of the pigment recrystallizes and causes opacification on cooling from the firing process.

In formulating holloware enamels, the degree of acid resistance required is less than for chemical plant, for example, reaction vessels. Consequently the  $\text{RO}_2$  ( $\text{SiO}_2$  and  $\text{TiO}_2$ ) is lower, thus permitting increased quantities of fluxes to be fired at lower temperatures and having superior chip resistance. Conversely, chemical plant enamels are higher in silica and dissolved titania and require harder firing. An example of such an enamel is shown in [Table 1](#).

The acid resistance required for domestic appliances varies with the particular component, for example, the oven interior of a gas cooker necessitates higher resistance than the outer sides – the former being at least Class A using 2% sulfuric acid while the latter can have a lower grading based on less aggressive citric acid tests. These tests are detailed in EN 14483-1:2004.

The enamel mill addition, degree of firing, and furnace atmosphere all affect acid resistance. An increase in clay and alkaline electrolyte detracts from this property and underfiring also has an adverse effect. The use of organic suspending agents is thus preferable to clays, from this aspect, but other factors must also be considered. Similarly replacement of 1% milling clay by 0.25% of the more colloidal bentonite is beneficial. Large additions of quartz at the mill improve heat resistance, and, provided the firing temperature is increased to dissolve a sufficient quantity of this silica in the glass, acid resistance is also enhanced.

In the glass-bottle industry bottles can be cooled in a dilute  $\text{SO}_2/\text{SO}_3$  atmosphere to increase chemical resistance. A similar effect has been noted with

vitreous enamel. It has been postulated that a thin layer of  $-OH$  groups or  $-OH-H_2O$  (hydronium) ions is adsorbed on the surface of fired enamel. These ions are transformed into  $-OSO_2$  or  $-OSO_3$  in the presence of oxides of sulfur which are more resistant to further acid attack. It is known that the acid resistance of a recently fired enamel improves with ageing, probably due to enamel reaction with  $SO_2/SO_3$  in the atmosphere and it is quite common for the grading to improve from Class A to Class AA (EN 14483-1:2004).

In enamels for chemical plant such as autoclaves, it is not only the degree of acid resistance which is important but also the freedom of the finish from minute flaws detectable by high frequency spark testing or chemical methods. Chemical methods depend upon a color change when the reagent such as ammonium thiocyanate reacts with the iron exposed at the bottom of the pinhole or flaw in the finish. Alternatively, an electric cell can be formed via the exposed iron in the flaw and detected chemically.

In general, strong mineral acids are more severe in their attack on enamel than weak organic acids. Vargin<sup>3</sup> has stated that the severity of action of organic acids on enamel increases with the increase in the dissociation constant of the acid. Temperature plays a major part in acid resistance – the nearer the boiling point the greater the rate of attack. It is more significant than acid concentration.

It is recognized that vitreous enamel possesses good acid resistance, but an exception is hydrofluoric acid. This is due to the relative ease of reaction between this acid and the silica (which is the largest constituent in the frit) to form silicon tetrafluoride. This reaction is made use of in some 'de-enameling' plants.

### 3.28.3.3.2 Alkali and detergent resistance

The usual method of de-enameling sheet iron is by immersion in fused or hot strong aqueous solutions of caustic soda where the silica network is broken down to form sodium silicate. However, in spite of this fact, enamels are capable of withstanding detergents and mild alkalis and this finish is often used very successfully in washing machines, baths, sink units, etc. where alkaline conditions prevail. Such enamels are usually higher in alumina than acid-resisting enamel and often contains zirconia in the frit. Other elements which aid alkali resistance are barium, calcium, lead, and zinc, and their function in this context is to increase the bond with the essentially silica network and form insoluble silicates which act as a protective coating slowing down the formation of soluble

sodium silicate. The necessity for alkali resistance is relatively limited when compared with detergent resistance and it has been shown that while these two properties are similar, a finish resistant to one is not necessarily a resistant to the other.

The Institute of Vitreous Enamellers produced a report on detergent resistance in 1959<sup>5</sup> and the following facts are brought out:

1. Semi-opaque acid-resistant titania enamel and alkali-resistant frit generally have good detergent resistance whereas non-acid-resistant sign enamel and  $Al_2O_3/B_2O_3/P_2O_5$ -based finishes have poor resistance.
2. Initially, detergent attack is accompanied by a deposit on the enamel surface which can be abraded off resulting in an apparently unaffected glossy appearance. This contrasts with acid attack when a progressive weight loss occurs and original gloss cannot be restored once it has been lost or diminished. After more prolonged detergent attack it is not possible to restore the original high gloss.
3. The rate of attack is very dependent upon temperature. At boiling temperature it is several times greater than that at room temperature.
4. An increase in milling clay has a marked effect on improving this property.
5. Increased detergent concentration, coarser grinding of the frit, and nonstandard firing all cause minor deterioration in resistance.

In the design of an enamel for a washing machine tub, detergent resistance alone is not sufficient and the enamel must also be capable of withstanding the possible abrasive action of buttons, zip fasteners, etc.

### 3.28.3.3.3 Resistance to water and atmosphere

These properties are of particular importance in enameled signs, architectural panels, cooking utensils, and hospital ware subjected to repeated sterilization. That such enameled signs as 'Stephen's Inks', etc. are still in existence and in good condition after many years of outside exposure coupled with the fact that the use of vitreous enamel as a finish for architectural panels is growing, are ready pointers to the good water and atmospheric resistance of enamel. Enameled hospital utensils such as kidney bowls score over organic finishes because of ease of sterilization and also because they are less accommodating to germs, bacteria, etc. on account of their lower electrostatic type attraction for such microbes.

Action of water on enamel is in many ways similar to that of acids in that the network modifier is the weak link and through hydrolysis can be removed from the glass system resulting in loss of gloss and porous surface. As with acids and alkalis, attack on the glass by water can be continued in extreme cases, by an attack on the inorganic coloring matter initially liberated or made more active. In an enclosed system the soluble salts first leached out from the enamel by water become in turn the corrosive element and further attack is dependent upon the pH of such a salt, or, for example, on the  $\text{Na}_2\text{O}/\text{B}_2\text{O}_3$  ratio.

Introduction of divalent calcium and barium oxides into frits in preference to monovalent sodium and potassium generally increases water resistance. Further, oxides of tetravalent and pentavalent metals have a favorable effect on the resistance of glasses and enamel to water. The influence of  $\text{B}_2\text{O}_3$  and fluorine in the frit on chemical resistance is variable and is dependent upon the content and balance of the frit constituents, but they usually cause diminution in resistance. In general, mill-added clay, silica, and opacifier increase water resistance provided the firing or fusing of the enamel is at the optimum.

As is expected, atmospheric resistance is related to water and the acid formed from  $\text{CO}_2$ ,  $\text{SO}_2$ ,  $\text{SO}_3$ , etc. The action of ultraviolet light has no apparent effect on vitreous enamel unlike the case with organic finishes.

There is good correlation between atmospheric and acid resistance, and this fact is helpful to manufacturers of architectural panels as they can easily and quickly determine the latter property and do not have to carry

out lengthy exposures to relatively unpolluted air. An exception, however, occurs with reds and yellows where strict correlation is not always true, and in these cases a test based upon exposure to a saturated copper sulfate solution under illumination by a white fluorescent light has been advocated.

In the main the comments recorded in this section apply to enamel fused onto sheet and cast iron. Enamel is, however, applied to aluminum, stainless steel, copper, and noble metals on account of its aesthetic value and also to confer durability to the base metal. With low melting point metals such as aluminum it is obvious that superb resistance to chemicals is not as feasible as in the case of iron as the base. Nevertheless, such metals are vitreous enameled in growing quantities and sold, indicating that the range of color and durability obtained is superior to that possible with alternative finishes.

It can justly be claimed that vitreous enamel coating applied to sheet or cast iron (or indeed any other metal) will confer to the basic shape color, gloss, texture, and high degree of resistance to corrosive influences.

### 3.29.1 Introduction

Ceramic materials have been used for many years as linings to process equipments, chimneys, and chemical resistant flooring. The materials utilized have been both man-made and naturally occurring. By using ceramics, the engineer is employing a material which offers excellent corrosion resistance, abrasion and impact resistance, as well as (generally) an excellent thermal barrier.

Chemical resistant masonry is generally emplaced to act as a barrier to prevent corrosion of a substrate, which is most commonly steel but may also be any suitable structural material such as concrete or glass reinforced plastic. The protection system, therefore, acts effectively as a lining that generally comprises multiple layers supported by a shell (i.e., the substrate) that provides strength and rigidity. The lining system that prevents corrosive chemicals from reaching the shell generally consists of a membrane and one or more layers of chemical resistant bricks, bonded with a chemical resistant mortar. The three products used in chemical resistant construction are therefore:

1. chemically inert ceramic products such as brick, stone or blocks,
2. chemically resistant mortars,
3. chemically resistant membranes

Traditional ceramic materials are usually derived from clays and are thus based on silicate/silica chemistry. They can be classified into structural ceramics, such as pottery, porcelain, refractories, glasses, etc.; and inorganic binders such as cements, gypsum, etc. Most of these materials consist of crystallographic grains of one or more phases that are bound together by another phase that is commonly glassy and melts at the sintering temperature for the material.

That corrosion/degradation of ceramics and glasses does occur is incontrovertible. However, it is important to remember that, unlike in metals, it is a chemical dissolution process and not an electrochemical process. Thus, the dominant controlling mechanisms for the degradation of ceramic materials are the

rate of the surface chemical reactions and the rate of diffusion of reacting species to and from the surface.

### 3.29.2 Ceramic Masonry Linings

#### 3.29.2.1 Chemically Resistant Bricks

##### 3.29.2.1.1 Acid-resistant brick

The man-made chemical resistant ceramic products generally offered are of two types, categorized by the raw materials from which they were manufactured:

- red shale acid-resistant products
- fireclay acid-resistant products

These products, often referred to as 'acid brick,' are visually identified by their respective colors of red and off-white. Historically the red shale products have been favored by British and North American manufacturers. The fire clay products are manufactured often as a refractory by-product. Their properties are dependant upon the structure of the raw material and the manufacturing methods. Both products are manufactured from clays containing low levels of acid soluble components. By firing at relatively high temperatures and by prolonging the firing time these products become partially vitrified throughout the entire body of the brick. This produces a strong brick with low water absorption, which is practically chemically inert ([Table 1](#)).

The performance of these ceramic products is very similar although differences exist due to their relative density and porosity. The red shale product being a highly vitrified dense bodied ceramic is excellent in applications covering a wide range of acid concentrations and temperatures. Red shale bricks have a surface porosity of practically zero percent, preventing penetration of chemicals into the body of the ceramic avoiding chemical spalling. The fireclay materials that have lower levels of flux within the clay generally fire to lower degrees of vitrification and hence exhibit higher porosity. As a result fireclay bricks unfortunately are susceptible to chemical spalling, as their relatively high porosity extends throughout the body of the brick. Chemical spalling is the

**Table 1** Typical physical properties of red shale and fireclay bricks

Property	Test method	Red shale	Fireclay
Density ( $\text{Mg cm}^{-3}$ )	ASTM C 20	2.45	2.15
Water absorption (%)	ASTM C 20	2	5
Apparent porosity (%)	ASTM C 20	5	11
Cold crushing strength (MPa)	ASTM C 133	>150	>80
Acid solubility (%)	ASTM C 279	7	6
Thermal spalling (no. of cycles at 450 °C)	DIN 51068	5	10

result of crystallization of salts that have penetrated the brick. The crystal growth weakens the structure of the brick causing it to fracture. The thermal spalling resistance of red shale is lower than that of the fireclay product. The fireclay products being more open bodied give improved thermal spalling resistance. They are often used in 'refractory' applications. Thermal spalling is not a problem normally encountered in liquid phases, where temperatures are generally below 150 °C. Due to its low porosity the red shale product usually conforms to the standard Type III in ASTM C 279. The fireclay product is described as meeting Type II in ASTM C 279.

Both products are manufactured in a variety of different shapes. The shapes can be specifically manufactured to suit the complex arrangements often found in chemical reaction vessels. The two products are used in similar applications; the choice between them generally made purely on economic considerations.

### 3.29.2.1.2 High-density fireclay

This material is similar to the low density fireclay, however, the density is increased to 2.3 Mg m<sup>-3</sup> and the porosity lowered to 5%. As a result the cold crushing strength is improved as is the acid solubility. The somewhat improved performance over the two previously mentioned products is offset by a considerable increase in cost.

### 3.29.2.1.3 Carbon/graphite

Carbon brick is used in conditions where shock resistance is of prime importance. Due to their much higher porosity and lower coefficients of expansion these materials are capable of withstanding thermal and pressure shock to a much higher degree than those products previously mentioned. Carbon brick can be used to absorb surface stresses in brick linings which would otherwise cause compressive failure of red shale or fireclay bricks. Carbon brick also exhibits resistance to attack by both strong alkali and hydrofluoric acid.

Carbon brick is generally derived either from coking coal or from petroleum coke. The petroleum cokes offer a higher purity containing very low levels of ash. Often clays are used as binding agents during brick manufacture. The nature of the ash and binding agent must be considered when specifying carbon brick types as they will alter the chemical resistance of the brick. In particular the resistance to strong alkali and hydrofluoric acid can be adversely affected by the composition of the ash or binding agent. Carbon brick is generally stable to very high temperatures in the absence of an oxidizing atmosphere. However, in air the temperature limit for carbon brick is 350 °C, above which the carbon brick will be destroyed by oxidation to carbon dioxide (Table 2).

### 3.29.2.1.4 Silicon carbide

Silicon carbide brick is made from SiC (80–90%) normally nitride bonded with Si<sub>3</sub>N<sub>4</sub>. This relatively high porosity material gives good thermal spalling resistance along with a general high chemical resistance. The bricks and special shapes made from this product can be used at high temperatures where high abrasion resistance is required (although alumina brick can offer a slightly higher abrasion resistance) (Table 3).

### 3.29.2.1.5 Foamed glass

Foamed borosilicate glass or aluminosilicate glass is formed into blocks which have zero percent water absorption. This is a highly efficient impermeable insulating material with good chemical resistance to all acids, except hydrofluoric acid. This product cannot be used in the presence of alkali solutions. Foamed glass offers a very good thermal barrier having a particularly low thermal conductivity. Foamed glass blocks are available in a variety of different shapes and grades. The grading of the product is related to its density. Foamed glass blocks can be easily cut with a 'wood' saw. The application of this material is limited by its extremely low crushing strength and abrasion resistance (Table 4).

**Table 2** Typical physical properties of carbon bricks

Property	Petroleum-derived coke	Coal-derived coke
Bulk density (Mg m <sup>-3</sup> )	1.50	1.60
Apparent porosity (%)	25	19

Thermal diffusivity	ISO8302	$4.2 \times 10^{-7} \text{ cm}^2 \text{s}^{-1}$

### 3.29.2.1.6 Alumina

Fine grain, high grade alumina shapes are manufactured from an exceptionally pure, uniformly controlled alpha aluminum oxide and are engineered to be one of the best wear resistant materials available to counteract fine particle abrasion. Preengineering and advanced processing techniques enable the manufacture of alumina products in a variety of geometries from simple to complex shapes. Grid support beams and packing internals for sulfuric acid towers are normally manufactured from high alumina clays ([Table 5](#)).

### 3.29.2.1.7 Porcelain

Similar to high alumina brick, porcelain is an extremely dense material manufactured from high alumina content materials (85%). Its zero water absorption and excellent chemical resistance can be put to use where it is important to maintain product purity. The density of this product generally exceeds  $2.45 \text{ Mg m}^{-3}$ .

### 3.29.2.1.8 Silica

High silica content bricks (>98%) can be used for a wide range of very high concentration acids. Their

At 400 °C	0.215	0.725

use must be avoided in the presence of hydrofluoric acid and strong alkali. They are available as both a high density product and also as a low density silica product. The low density product combines excellent chemical resistance with good thermal insulating properties ([Table 6](#)).

### 3.29.2.1.9 Cast basalt

Basalt rock is quarried, crushed, and then melted and poured into moulds. Extremely complex shapes can be manufactured. This product offers excellent chemical resistance and abrasion resistance. It is used for lining bunkers, hoppers, and chutes carrying abrasive chemicals ([Table 7](#)).

### 3.29.2.1.10 Granite

Granite has been used for centuries as a chemical resistant block. Simply cut to shape from deposits of granite rock this product can be used in a variety of different chemical and abrasion resistant applications. The properties of granite can vary immensely from one source to another. Large shaped granite blocks have found use throughout the steel industry as 'skid blocks' in steel pickling tanks ([Table 8](#)).

### 3.29.2.1.11 Refractory bricks

A large range of refractory bricks are manufactured throughout the world. They are occasionally used in chemical resistant linings acting normally as an

insulating brick behind the ‘true’ chemical resistant brick. The manufacturers do not list chemical resistance amongst the properties of these products. Their physical properties vary greatly from one product to the other. When designing chemical resistant linings using these products their selection should consider the following points: (1) the type of chemicals likely to contact the product should not damage the product. Higher temperatures can increase the chemical solubility of the product. (2) The compressive stress that the brick will experience must be below the compressive strength of the brick. (3) The thermal conductivity and brick thickness should be as much as needed to give the required temperature drop. The products used most commonly in chemical resistant construction include the following:

*Insulating firebricks* are manufactured from low iron silica/alumina clays. They have properties of low density and high porosity. Having high porosity makes them unsuitable in applications where total immersion in liquid chemicals is a probable condition. Their temperature range can extend to 1000 °C.

*Mullite bricks* are manufactured from clays having a preponderance of alumina over silica. Hence, the fired bricks contain little free alumina. The partial vitrification produces a brick offering good chemical resistance and high compressive strength. These bricks can be used in low duty chemical resistant applications when ‘acid brick’ is not available.

### 3.29.2.2 Mortars

#### 3.29.2.2.1 Silicate-based mortars

In chemical resistant masonry construction the choice of mortar is determined by the chemical and thermal conditions of the process. Care must be taken when using these mortars, as deviation from the manufacturers mixing instructions and recommendations regarding their use can result in a mortar with poor strength and chemical resistance.

These mortars consist of sodium or potassium silicate liquid mixed with a silica filler. The hardening process is accelerated by the use of a catalyst, for example, polyphosphate, silicofluoride, amines, and lead oxide. The advantage of polyphosphate hardened mortars is a low fluid absorption (2% for sodium polyphosphate). Potassium silicate mortars, utilizing silicofluorides must be washed with weak acid as part of the curing process. This also assists in lowering the fluid absorption.

These mortars have excellent chemical resistance to low and high concentration acids. Their temperature limit is 800 °C. A disadvantage of these mortars is their high porosity >12%. They are not suitable for contact with hydrofluoric acid and alkali solutions. Potassium silicate mortar is the most widely used. The use of sodium silicate mortar has declined due to its relatively high water solubility. With the addition of suitably graded fillers the potassium silicate mortar can be modified to produce a potassium silicate concrete that can be cast in a similar manner to Portland cement (Table 9).

#### 3.29.2.2.2 Synthetic and natural resins

##### Furane resin

Furane resin mortars have found wide popularity in the United Kingdom and North America due to their excellent chemical resistance and ease of use. This is the standard mortar for low sulfuric acid concentration (<70%) applications in vessel linings and flooring. They consist of furane resin liquid mixed with filler. The fillers available are silica, graphite or carbon. The normal filler is silica. For hydrofluoric acid and hot concentrated alkaline conditions carbon filled grades of furane mortar should be used. The carbon filled variety of this mortar is the mortar of choice when bonding carbon brick. The cheaper silica filled furane resin mortar should always be used when bonding acid brick. Furane mortars offer good erosion resistance and a service temperature of up to 200 °C. Some specialist furane mortars can withstand temperatures up to 300 °C (Table 10).

**Table 9** Typical physical properties of potassium silicate mortar

Property	Value
Density ( $\text{Mg m}^{-3}$ )	>1.85
Tensile strength (MPa)	3.5
Compressive strength (MPa)	>21
Modulus of rupture (MPa)	10
Coefficient of expansion ( $\text{K}^{-1}$ )	$15 \times 10^{-6}$
Water absorption (%)	15
Temperature limit ( $^{\circ}\text{C}$ )	800
Conformance	ASTM C 466

Bond strength (MPa)	1.5
Density ( $\text{Mg m}^{-3}$ )	1.985
Water absorption (%)	0.2
Temperature limit ( $^{\circ}\text{C}$ )	200
Conformance	ASTM C 395

**Modified phenolic resin**

Phenolic mortars offer chemical resistance over a wide range of both acid and alkali conditions. A choice of either carbon or silica based fillers are available. Being phenol based, care must be taken when using these mortars. In recent years the safety precautions required when using this mortar have resulted in a reduction in its use. Graphite filler and a double hardener system permit this mortar to be utilized in prestressing brickwork which places the brick lining in permanent compression. The porosity of these mortars is extremely low. They exhibit a good degree of erosion resistance and have a maximum service temperature of  $190^{\circ}\text{C}$  (Table 11).

**Epoxy resin**

Epoxy resin mortars are supplied as a two- or multi-component system. The chemical resistance of these mortars is good. They can be used to withstand medium strength acid and alkali. They exhibit extremely high bond strength between brick and steel. Epoxy mortars are limited by a maximum temperature of  $90^{\circ}\text{C}$ . Epoxy resins have found extensive use as monolithic screed coatings for concrete in flooring applications (Table 12).

**Table 11** Typical physical properties of phenolic resin mortar

Property	Value
Tensile strength (MPa)	3
Compressive strength (MPa)	44
Bond strength (MPa)	1.2
Density ( $\text{Mg m}^{-3}$ )	2
Water absorption (%)	0.3
Temperature limit ( $^{\circ}\text{C}$ )	190
Conformance	ASTM C 395

**Table 12** Typical physical properties of epoxy resin mortar

Property	Value

Bond strength (MPa)	2.0
Density ( $\text{Mg cm}^{-3}$ )	2
Water absorption (%)	0.3
Temperature limit ( $^{\circ}\text{C}$ )	90
Conformance	ASTM C 395

**Polyester resin**

This family of mortars includes bisphenols, chlorinated polyester and vinylester based products. These mortars offer good resistance to acid, especially oxidizing acids. They have poor resistance to organic solvents with the exception of acetic acid. Epoxy mortars have better resistance to organic solvents. The bond strength is equivalent to epoxy. The compressive strength of polyester mortar is the highest of all resin based mortars (65 MPa).

**3.29.3 Chemically Resistant Membranes**

The membrane is the final line in defense for the shell and the first material in the system to be applied during installation. The membrane should, where possible, be impervious. Its selection, however, is often determined by temperature and chemical resistance considerations.

**3.29.3.1 Asphalt/epoxy Mastic**

A nonrigid material is applied directly to the vessel shell. The degree of flexibility is generally governed by the amount of epoxy and hardener that is used in the mix. Asphalt and bitumen are often used on their own as a membrane for chemical resistant floors.

**Table 13** Typical physical properties of PTFE sheet

Property	Value
Density ASTM D 792 ( $\text{Mg m}^{-3}$ )	2.1–2.2
Water absorption ASTM D 570 (%)	<0.01
Tensile strength ASTM D 638–D 1708 (MPa)	25–30
Elongation ASTM D 638–D 1708 (%)	250–400
Tensile modulus ASTM D 638–D 1708 (MPa)	750
Flexural modulus ASTM D 638–D 1708 (MPa)	44–52
Coefficient of linear expansion ASTM D 696 ( $\text{K}^{-1}$ )	$10\text{--}15 \times 10^{-5}$
Thermal conductivity ASTM C177 ( $\text{W m}^{-1} \text{K}^{-1}$ )	0.2–0.45

### 3.29.3.2 Ceramic Paper/Potassium Silicate

The ceramic paper (high purity chemical resistant paper made from aluminosilicate refractory fibres) is soaked in sodium silicate and pasted onto the substrate in sheets (similar to applying wallpaper), forming an impervious membrane. This membrane is often used in high strength acid applications. Temperature resistance is excellent.

### 3.29.3.3 Fluorocarbons

Fluorocarbons, such as PTFE and PVDF, offer excellent chemical resistance and thermal resistance up to  $250^\circ\text{C}$  and are applied usually in sheet form. Given their intrinsic 'nonstick' surfaces, their use is limited by the performance of the bonding agent either epoxy or asphaltic mastic. Often the surface of the sheet is 'etched,' to improve bonding. The sheet thickness is often very thin: 0.125 or 0.25 mm (Table 13).

### 3.29.3.4 Lead

For best performance, this excellent membrane should be homogeneously applied. In service, temperatures must be kept below  $70^\circ\text{C}$  to avoid creep. A lack of personnel with the necessary installation skills has led to a reduction in the use of lead as a membrane.

### 3.29.3.5 Thermoplastic

Sheets of a thermoplastic material such as Hypalon (chlorosulfonated polyethylene) may be applied to the shell with adhesive. Being a thermoplastic material the joints may be welded and the sheets are often reinforced with a polyester scrim. This membrane is nonrigid and has an upper limit of sulfuric acid

**Table 14** Typical physical properties of Hypalon sheet

Property	Value
Breaking strength ASTM D751 (N)	500
Tongue tear ASTM D751 (N)	250
Temperature resistance (high) ASTM D2136 ( $^\circ\text{C}$ )	160
Water absorption (%)	3.0
Density (for black unreinforced) BS903 ( $\text{Mg m}^{-3}$ )	1.6
Thermal expansion coefficient ASTM C864 ( $\text{K}^{-1}$ )	$20 \times 10^{-5}$
Thermal conductivity ( $\text{W m}^{-1} \text{K}^{-1}$ )	0.11
DC electrical resistivity at $125^\circ\text{C}$ ( $\Omega \text{cm}$ )	$2.3 \times 10^{11}$

concentration of 70%. It may be used as a membrane for both vessel and flooring applications (Table 14).

### 3.29.3.6 Glass Fiber Reinforced Resins

These are rigid membranes. The glass fiber reinforces furane, phenolic, or epoxy based compounds to reduce the susceptibility to hairline cracks.

### 3.29.3.7 Rubber

Either hard or soft rubbers, both natural and synthetic can be used as membranes behind acid bricks. They are not suitable for high acid concentrations and have temperature limitations of  $90^\circ\text{C}$ . Petroleum products can damage butyl rubber. PVC can be used in the presence of oxidizing chemicals. There are numerous types of rubber available; the most popular being bromobutyl, chlorobutyl, and neoprene. These products are often combined to produce calendered sheets which are frequently used to protect steel substrates. A bromobutyl/neoprene rubber sheet membrane (neoprene as the backing sheet to give improved bond strength) has found great success in lining vessels for the metallurgical industry (Table 15).

## 3.29.4 Design and Construction of Ceramic Masonry Linings

Ceramic masonry lining systems are utilized extensively to prevent corrosion of vessel shell materials, chimney shell materials and concrete floors. This is an extremely complex subject which cannot be effectively dealt with in this publication. The following guidelines will be of use to the engineer involved in the design of ceramic masonry corrosion resistant linings. The engineer is recommended to approach

**Table 15** Typical physical properties of BIIR/CR rubber sheet

<i>Property</i>	<i>Value</i>
Tensile strength (MPa)	$\geq 7$
Elongation at break (%)	$\geq 350$

the ceramic product manufacturer, the membrane manufacturer, the mortar manufacturer and the specialist installer for advice regarding ceramic lining design.

### 3.29.4.1 Vessel Linings

A multitude of different structures may require lining after specification. The most important fact to be remembered when designing ceramic lined structures is that the most likely form of failure is tension or shear. Ceramic lined units must, therefore, be designed to make the most of the excellent properties of compressive *strength* shown in ceramics and avoid possible tensile failure of the lining.

General process parameters will determine the type of mortar, membrane and ceramic material to be utilized. Once these have been specified the thickness and number of layers of brick must be determined. Temperature gradients must be calculated in order to check the membrane and substrate temperatures thus avoiding excursions beyond material performance limits. Stress-strain calculations can be performed to determine the structural integrity of the lining system.

Vessels are generally cylindrical, offering curved surfaces to be brick lined. This is an ideal situation, provided the thermal expansion of the shell is kept under control when the brickwork will be placed into compression during operation. Circular bricks should be used against curved surfaces. The use of thin tiles as backing courses and square bricks on tapered joints is not recommended due to the difficulty of transferring the stress evenly. This 'cheap' design which has been adopted recently by some manufacturers/installers is prone to movement resulting in shear which causes cracking of the mortar joints and tiles.

The bases of vessels are often flat. A superior base design is a dished base lined with at least two layers of brick, generally radial end arch bricks installed in concentric circles or radial stretchers installed in a cruciform arrangement. If a flat base is a necessity then multiple layers of bricks must be utilized if lifting of the lining is to be avoided.

Great care must be taken in designing the ceramic brick elements used in forming nozzles and manholes. The use of special shaped ceramic units for this application is highly recommended. Forming nozzles by cutting standard bricks during installation can only be successful provided an extremely skilled craftsman performs the work.

A number of specialist vessels may require supports for packed beds. Due to their excellent corrosion resistance ceramic products are utilized to form support structures for tower packing in sulfuric acid plant drying and absorption towers. Two designs are currently available:

- (i) support wall and beams
- (ii) self supporting dome

The first method has an extremely successful track record. The use of the self supporting dome, however, has led to gas channeling at a number of installations, especially on larger diameter towers. The ceramic product is a most effective product for this structure. The design choice is left with the engineer.

To optimize the corrosion resistance of the lining it is essential that the ceramic masonry lining is installed by experts following strict guidelines issued by the manufacturers of the lining components. The guides will cover a number of important areas, including vessel shell construction and preparation, material storage, mixing of products, installation technique for the membrane, mortar and brick, the curing process and inspection. The following general guide is the basis for all ceramic masonry lining systems.

#### 3.29.4.1.1 Fabrication of suitable steel vessels

All welded joints shall be continuous and ground smooth to a minimum of 3 mm radius for convex corners and to a minimum of 6 mm radius for concave corners. All surfaces shall be free of weld splatter of foreign material. Voids, gaps, holes, pockets, or undercut welds are not permitted. Vessels should be fabricated to an appropriate constructional code, for example: PD5500 (UK), GOST (Russia), ASME VIII (USA), AD2000 (Germany), ODAP2000 (France).

### 3.29.4.1.2 Storage of materials

Where possible, all materials to be used in the brick lining shall be stored in such areas and under such cover as to prevent water from entering any of the packages or from soaking the brick. In addition, for 16–24 h before use, all materials shall be maintained at temperatures not below 16 °C (in cold weather) or above 32 °C (in hot weather). If the materials have become damp (e.g., during transportation) then they must be thoroughly dried with blown dry air before use.

### 3.29.4.1.3 Surface preparation

Prior to applying the membrane, the contractor shall prepare the surface to be lined in accordance with SSPC-SP10 or SA 2½; blast cleaning should be carried out using silica grit to ensure that the surface is free of all rust and foreign matter. Following cleaning, all dust and silica shall be removed. The surfaces to be lined shall be fully dry and, if necessary, dried to achieve this.

### 3.29.4.1.4 Application of a membrane

The membrane must be applied before the steel surface develops a visible rust film. Any rusted surface must be cleaned again. Spot cleaning may be done by wire brushing followed by solvent cleaning. The membrane is installed in accordance with the manufacturer's recommendations. For sheet rubber membranes, this operation may require specialist rubber lining labor.

### 3.29.4.1.5 Mortar

The mortar shall be mechanically mixed in the ratio quoted on the manufacturer's specification sheet. No water or other foreign matter or unauthorized fillers, extenders or fluids shall be added to the mix. Mixing equipment shall be clean at the start of mixing and all surplus or unused mortar shall be removed between batches to prevent excessive inter-batch contamination and retempering of spent mortar.

In general, the mortar shall be completely free of lumps, dried mortar particles and foreign material. The mortar shall be capable of being spread uniformly over a brick surface without dragging. When the set of the mortar has advanced to the point that it will no longer wet the brick properly, no more of that batch shall be used and the balance shall be discarded.

### 3.29.4.1.6 Brick laying

All cutting of brick shall be done with a brick saw outside the vessels to prevent chips and small

particles from falling on the membrane backing. After cutting, all brick shall be fully air dried, wiped with an absorbent cloth and mortared into position when dry.

All joints shall be full and tight, the brick double buttered (i.e., all brick surfaces in mortar joints or against vessel membrane shall be buttered on both surfaces) and pressed firmly in place. All bricks shall be laid with a sliding motion to eliminate the possibility of air pockets and shall be firmly pressed into place and tapped until all surplus mortar is forced out of joints. Any excess mortar must be cut off cleanly with a trowel before initial set takes place. This mortar may be used to butter brick surfaces. Excessive waste of mortar must be avoided.

Large joints are unacceptable. The mason should aim for 3–4 mm joints. The width of mortar will be checked by an inspector. The top surface of brick shall not be coated with mortar until the next course of brick is placed. At the start of brickwork each day, all surplus mortar projecting from end joints of brickwork laid on the previous day shall be struck off the area on which the new brickwork is to be applied. Joints between courses and layers shall be staggered for maximum strength and to eliminate the possibility of straight line penetration from the interior directly to the vessel wall.

The brick lining subcontractor shall maintain proper material and internal air temperatures, and provide for full cure time as required by the mortar manufacturer. No bricks shall be laid when the temperature is less than 3 °C above the dewpoint and during winter time, all work areas shall be kept at a minimum temperature of 21 °C day and night until the mortar has set. No excessive moisture is acceptable (such as condensation on the steel plate in the vessel) where bricks are being installed. Condensation may be prevented by portable heaters (preferably electric) inside the vessels. Any brickwork less than 5 days old which has been wetted shall be replaced. Care should be taken to prevent condensation on or behind the brickwork from blowers or other devices used for heating.

The following is a guide to hardening time for potassium silicate mortar:

Temperature (°C)	Time (days)
10	10
16	8
21	6
27	4

In order to develop the optimum mortar strength, the curing shall be a minimum of 6 days or the above guide time, whichever is longer. After the completion of curing, the joints (when using potassium silicate mortar) shall be washed with 10% sulfuric acid to protect the surface against moisture or high humidity damage, unless the equipment is being placed immediately into acid service. Please note that acid washing of potassium silicate mortar is a vital part of the curing process and must not be omitted. Furane based mortars do not require acid washing.

All waste materials, spoiled and unused brick and mortar, water and cleaning materials shall be kept away from all acid proof masonry until it is cured.

#### **3.29.4.1.7 Inspection and quality control**

Work areas (mixing, brick cutting and installation areas) shall be maintained sufficiently clean so that foreign matter is not introduced into the lining system. Adequate lighting shall be maintained in the vessel during installation work to enable a sound lining to be obtained in accordance with this standard. The work will be inspected by the client's inspector at the following stages:

1. before the application of membrane, to ensure that all metal surfaces are clean and dry;
2. after the application of membrane, to ensure that complete coverage has been achieved;
3. during the laying of brick, to ensure that the specified conditions are followed.

Lining installations which are not in accordance with the specification or in which injurious defects, improper application, or excessive repairs are indicated shall be subject to rejection. A full inspection report shall be submitted to the manufacturer prior to the equipment being placed in service.

#### **3.29.4.2 Linings to Flooring, Pits, and Trenches**

Ceramic masonry lining systems have been successfully utilized to protect floors, pits, and trenches from the action of corrosive chemicals for many decades. Just as with vessel lining systems the total package consists of the three main components – membrane, brick, and mortar. The specification of the three component is entirely dependant upon the process conditions; taking careful consideration of the chemical types, temperatures and exposure times. Correct product specification, design and installation technique will produce a corrosion resistant lining which will

maintain many years of trouble free service. The lining offers not only corrosion resistance but also thermal resistance, abrasion resistance and impact resistance. The use of an acid brick system will permit heavy loading such as those experienced in chemical tanker loading bays.

For the majority of applications an asphalt/epoxy membrane, acid brick and furane mortar are used for the lining system. The membrane and mortar can be altered to suit specific process conditions. For high concentration acids Hypalon sheet membrane is often specified. In the presence of hot alkali or hydrofluoric acid carbon bricks may substitute acid bricks.

Both acid brick and acid tile are used for masonry lining systems. A tile is recognized internationally as a masonry unit with a thickness of 30 mm or less. Tiles are available in most of the materials mentioned previously for brick products. Their corrosion resistance is material and manufacturing method dependant. The choice between brick or tile is primarily one of determining the appropriate thickness of the masonry unit for the application. The thickness of the masonry unit must be sufficient to offer structural stability, mechanical protection and thermal protection.

It is worth stating, again, that ceramic masonry lining systems offer excellent performance provided they are placed in *compression*. Tensile and shear stresses are unacceptable. It is therefore essential that the substrate to which the ceramic masonry lining is to be applied has sufficient strength and rigidity to support the lining under all anticipated loads. In order to achieve sufficient rigidity it is recommended that the floor, pit or trench be constructed from reinforced concrete. The use of sheet steel, wood or concrete blocks as a substrate is unadvisable.

Concrete floors generally contain expansion and construction joints to permit movement. These joints must be mated to similar joints in the ceramic masonry lining. The joints are a potential source of leakage and therefore serious corrosion to the underlying substrate. The positioning of the joints, the material used for the joints and the design of joints is important if the integrity of the floor is to be maintained. The manufacturers should be consulted over the design of chemical resistant expansion joints.

There a number of corrosion resistant expansion joint materials available. The type of compression/expansion must be considered when specifying the joint material. Many joint materials deform under compression and then protrude from the joint. This would be totally unacceptable in enclosed joints, which may be employed in multi layer brickwork

systems. In a single layer brickwork system the protruding joint may be cut off. A brief list of the corrosion resistant expansion joint material, currently available, is as follows:

Plasticized PVC	Polyurethane foam	Natural rubber
Ceramic blanket	Silicone sealants	Teflon felt
Polyester foam	Flexible epoxy	Carbon sponge

Flexible epoxy has the best overall chemical resistance combined with a temperature resistance of 75 °C. For precise details of expansion joint corrosion and temperature resistance the manufacturer should be consulted.

### 3.29.4.3 Linings to Chimneys

Combustion processes invariably produce acid gases. In order to reduce energy wastage in power stations the flue gas temperatures have been steadily reduced over the last four decades. Flue gas desulfurization has also led to a reduction in flue gas temperatures. It is now commonplace to have flue gas temperatures below 90 °C, which is below the sulfuric acid and water dewpoints. As a result, acid condenses on the inside of the chimney causing corrosion of the flue liner and, hence, precautions against this occurrence have to be taken.

Ceramic masonry chimney linings serve as a chemical and abrasion resistant barrier against gases, liquids, and solids thereby protecting the chimney shell (windshield). There are generally three distinct lining systems for concrete or steel windshields:

- full height, free standing flues;
- multilevel flues (as single or multiflue systems);
- full height linings as an integral component of the windshield.

Lining materials are carefully chosen to suit the flue gas conditions. Nonmetallic lining materials include acid brick, foamed glass block, synthetic rubber and glass fiber reinforced resins.

Flues constructed entirely of acid brick and chemical resistant mortars (normally potassium silicate) have an excellent proven track record. They are the only nonmetallic material capable of withstanding high temperature gases and a wide variety of corrosive

chemicals. As free standing brickwork elements, unconstrained by an outer shell, the brick flues have a tendency to exhibit tensile failure, when operated at elevated temperatures. Large cracks in the brick flues are evidence of this type of failure. The use of interlocking bricks and high bond strength mortars has reduced the incidence of stress cracks in brick flues. With the advent of chimneys operating with low temperature flue gases, tensile failure is no longer a problem and the brick flues can give an extremely long trouble free service.

The key benefits of acid brick flues are:

- durability,
- suitability for use in FGD and non-FGD systems,
- cost effective,
- long service life,
- excellent track record.

A large number of chimneys, throughout the world, have been built either entirely of steel or a concrete windshield with steel flues. The production of acid condensates in the flue gases, due to lower flue gas temperatures causing serious corrosion problems in these chimneys. Most of these chimneys now require the installation of a corrosion protective lining. Due to loading limitations on the foundations, the large weight of acid brick and mortar precludes this product as a viable solution. Foamed glass blocks bedded and jointed in chemical resistant mortars offer a suitable answer to the problem of corrosion prevention. The foamed glass block combines light weight with excellent acid resistance and thermal insulation properties. The choice of chemical resistant mortar is dependant upon the flue gas conditions. The mortar can also be used as the membrane applied to the steel shell, behind the foamed glass blocks.

## 3.30.1 The Chemistry of Cement

### 3.30.1.1 Cement Types

EN 197-1:2000 defines cement as “a hydraulic binder, i.e., a finely ground inorganic material which, when mixed with water, forms a paste which sets and hardens by means of hydration reactions and processes and which, after hardening, retains its strength and stability even under water.” The hardening of cement is mainly a result of the hydration of calcium silicates and, to a lesser extent, of aluminates.

Portland cement consists of cement clinker and various other constituents, which determine its classification. These additional constituents can be granulated blast furnace slag, natural and industrial pozzolanic materials, burnt shale, limestone, silica fume, and calcium sulfate, which are added during the manufacture to control setting. EN 197-1:2000 covers 27 common cement products, which are grouped into five main cement types as follows:

- CEM I – Portland cement
- CEM II – Portland–composite cement
- CEM III – Blast furnace cement
- CEM IV – Pozzolanic cement
- CEM V – Composite cement

### 3.30.1.2 Compounds Present in Portland Cement

Ordinary Portland cement (OPC) is made up of the compounds listed in Table 1. The abbreviations are in the standard cement chemist’s notation: C = calcium

**Table 1** Compounds present in anhydrous cement

<i>Cement component</i>	<i>Abbreviation</i>	<i>% in OPC</i>	<i>Hardening rate</i>
Tricalcium silicate	C <sub>3</sub> S	>50	Rapid
Dicalcium silicate	C <sub>2</sub> S	<20	Slow
Tricalcium aluminate	C <sub>3</sub> A	<10	Rapid
Tetracalcium aluminoferrite	C <sub>4</sub> AF	<10	Extremely slow

oxide, S = silicon oxide, A = aluminum oxide, and F = iron oxide.

It is, however, more customary to express the composition of cements in terms of oxide analysis, that is, CaO, SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>, NaO<sub>2</sub>, and so on. From this it is possible to calculate the so-called 'Bogue compositions' shown in **Table 1**. The following equations are based on solving certain simultaneous equations and were first derived by Bogue.

For the system C<sub>3</sub>S–C<sub>2</sub>S–C<sub>3</sub>A–C<sub>4</sub>AF:

$$C_3S = 4.01710CaO - 7.6024SiO_2 - 1.4297Fe_2O_3 \\ - 6.7187Al_2O_3 (-2.852SO_3)$$

$$C_2S = 8.6024SiO_2 + 1.0785Fe_2O_3 \\ + 5.0683Al_2O_3 - 3.0710CaO$$

$$C_3A = 2.6504Al_2O_3 - 1.6920Fe_2O_3$$

$$C_4AF = 3.0432Fe_2O_3$$

The equations were produced by assuming that all the Fe<sub>2</sub>O<sub>3</sub> reacts with Al<sub>2</sub>O<sub>3</sub> and CaO to form the C<sub>4</sub>AF, the remaining Al<sub>2</sub>O<sub>3</sub> reacts with CaO to form the C<sub>3</sub>A. The CaO then reacts with the SiO<sub>2</sub> to form C<sub>2</sub>S and any CaO left reacts with the C<sub>2</sub>S to form C<sub>3</sub>S.

It should be recognized that in commercial manufacture, equilibrium conditions are unlikely to be achieved. Coarse particles may not be completely converted because some of the reactions occurring in manufacture are between liquid and solid phases and also resolution during cooling of previously crystallized phases may not be complete. Component parts may be embedded in each other where the liquid may not be able to act upon them or the liquid may crystallize independently without the formation of equilibrium products. The minor components of cements such as sodium, potassium, and magnesium oxides will also have an effect. Despite the aforementioned problems, the ability to produce a simplified equation for the composition of the

cement from its constituent parts has obvious benefits for the cement industry and also for scientific research.

### 3.30.2 The Hydration of OPC

#### 3.30.2.1 The Silicates

There is an empirical character to the information available with respect to the hydrolysis of the calcium silicates because of a wide variation in water contents and lime–silica ratios between component parts of the system. Also, products of the same composition can be represented by several phases, and it is difficult to prepare large crystals representative of those produced during cement hydration because the hydrates are in the form of gels.<sup>1</sup> In general, the reactions are considered to be as follows:

It is worth noting that Joisel<sup>2</sup> reports that there is no stoichiometrically defined hydrate of calcium silicate, and as a consequence, during hydration, intermediate compositions may exist locally between C<sub>2</sub>SH<sub>2</sub> and CH. Taylor<sup>3</sup> states that the composition of calcium, silica, and water varies between CS(aq.) and C<sub>3</sub>S<sub>2</sub>(aq.) without significant change in the X-ray diffraction pattern. It is the C–S–H that imparts the cementing action in concrete, derived from surface forces interacting over the large surface area of the C–S–H.

The rate of early hydration of silicates is controlled by the rate of dissolution of calcium and hydroxide ions into a liquid phase from the C–S–H layer produced around the cement grains.<sup>4</sup>

There is some debate whether or not the calcium silicate hydrate binds chlorides. Ramachandran<sup>5</sup> investigated the hydration of tricalcium silicate supplied by the Portland Cement Association in the presence of calcium chloride, using various techniques and concluded that there is evidence for the presence of various states of chloride. Ramachandran attributed this to two mechanisms: one due to the positively charged surface of the C–S–H adsorbing

negatively charged chloride ions and the second being the formation of some interlayer chloride, which was irremovable by leaching with ethyl alcohol but could be removed by leaching with water. Water molecules are more readily able to access the finer pores than does ethyl alcohol because of their smaller size. He added that the chloride ions incorporated into the C–S–H are not mobile enough in water to cause corrosion in reinforced systems.

Lambert *et al.*<sup>6</sup> used tricalcium silicate produced by firing a mixture of calcium oxalate, alumina, and magnesia to produce Jeffrey's Alite<sup>7</sup> ( $C_5S_16AM$ ), which is reported to be a reasonable approximation of  $C_3S$ . They reported, using pore water extraction to monitor the pore solution, that when the chlorides are added as sodium chloride no binding takes place. This is supported by the fact that the pH remained at  $\sim 12.5$ , which is the pH of saturated calcium hydroxide, which agreed with work done on microsilica binding using sodium chloride.<sup>8</sup>

### 3.30.2.2 Tricalcium Aluminate

Tricalcium aluminate is reported to preferentially react with calcium sulfate as follows:<sup>9</sup>

The term 'ettringite' has come into use in a generic sense to represent the calcium aluminate or ferrite trisubstituted hydrates (AFt) formed as a result of the reaction of tricalcium aluminate hydrating with gypsum and water.

If chlorides are present, the tricalcium aluminate mainly reacts with the sulfates present first to form the chloroaluminate,  $3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ , more commonly known as Friedel's salt.<sup>10</sup> It is worth noting that the formation of Friedel's salt will only take place if anhydrous tricalcium aluminate is present, and therefore, it would be expected that diffused chlorides will only be bound to a small extent. When tricalcium aluminate is hydrated in the presence of both gypsum and calcium chloride, a small amount of chloroaluminate is formed immediately, but the main consumption of chlorides begins only after the supply of sulfate ions is exhausted.

### 3.30.2.3 Tetracalcium Aluminoferrite

Tetracalcium aluminoferrite hydration is not well understood,<sup>11</sup> but is generally regarded as similar to the hydration of tricalcium aluminate under comparable conditions.  $Fe(OH)_3$  gel, AFt,  $C_2(A,F)H_8$ ,  $C_4(A,F)H_{13}$ , and  $Al(OH)_3$  gel have also been observed.  $C_4AF$  has a general formula of  $2CaO \cdot (Al_2O_3)_x (Fe_2O_3)_{(1-x)}$  where  $x$  is between 0 and 0.7. In most Portland cements  $x$  is usually 0.5.<sup>12</sup>

Ettringite is also produced and will undergo the same series of subsequent reactions as that formed during the tricalcium aluminate hydration. A chloro-ferroaluminate phase produced by the hydration of tetracalcium aluminoferrite in the presence of calcium chloride and analogous to Friedel's salt has also been identified.<sup>13</sup>

### 3.30.3 Stages in Cement Hydration

There are three main stages in the hydration of OPC.

#### 3.30.3.1 The First Stage

When OPC is mixed with water, a rapid reaction takes place, which forms a supersaturated solution. After this rapid period of initial hydration lasting less than 15 min, a period of very slow hydration lasting for several hours called the dormant or induction period occurs. There are four main theories for the cause of this period.

The first is that a layer of hydration products precipitate over the surface of the cement grains. After a period of time this splits, either by pressure caused by the formation of hydration products under this protective layer<sup>14</sup> or by osmotic pressure building up under the surface of the grain<sup>15</sup> and hydration commences again. The second theory states that hydration only starts when an initial hydrate of low permeability converts into one of a higher permeability<sup>16</sup> and therefore is similar to the first. The third proposes that the induction period ends because of calcium hydroxide crystallizing into solution, and thus forming nuclei that act as seed crystals for further calcium hydroxide, thereby allowing hydration of the silicates to proceed.<sup>17</sup>

The final theory reports that the induction period exists due to a potential barrier corresponding to a critical size of calcium silicate hydrate (C–S–H) nuclei.<sup>18</sup> According to this theory, C–S–H is initially only formed on imperfect preferential sites on the

surface of calcium silicates. Only after the hydrate nuclei reach a critical size does hydration extend to other parts of the surface and hence hydration accelerates.

The first theory is the simplest and has some evidence for its validity. Jennings and Pratt<sup>19</sup> concluded that, as hydration at the end of the dormant period is characterized by hollow spines growing out of the grains, this suggests that a membrane has ruptured and the interior of the grains flows out through these spines and hydrates on contact with the exterior solution. However, they also state that the environment of the experiment was artificial because it was at a water solids ratio of 20, and therefore, the procedure may be flawed although fibers such as those that were created in the experiment have been found in cement in practical situations. They suggest that when cement comes into contact with water, the calcium quickly passes into solution and a silica-rich layer forms a gelatinous coating containing alumina. This coating allows the passage of ions such as sulfates, potassium, and calcium along with water but not aluminum and silicon ions.

Odler and Dörr<sup>20</sup> studied the hydration of tricalcium silicate and concluded that the fourth theory was more accurate in this application. Addition of 'seed crystals' of calcium hydroxide did not affect the induction period, but the addition of prehydrated tricalcium silicate had a marked effect, thus discounting the third theory. They also stated that the preinduction period was controlled by the concentration of calcium hydroxide in the solution, and hence discounted the precipitation theory.

The time of inception and the duration of the dormant period depend mainly on the water–cement ratio, fineness of the cement, and its composition. The cement paste at this stage appears to be a suspension of fine powder in water. Odler and Dörr<sup>21</sup> state that the amount of tricalcium silicate that hydrates in the preinduction period can be altered by experimental procedure and the presence of defects in the crystalline lattice. The tricalcium silicate anneals with time, resulting in a lower number of lattice defects, resulting in an extension of the dormant period, thus further discounting the precipitation theory and supporting the final one.

During the dormant period a certain amount of sedimentation takes place, known as bleeding. This is undesirable because the water rises to the surface carrying fine cement particles with it, resulting in the formation of a high water–cement ratio slurry on the surface, called laitance, which has a low

strength. This causes problems when trying to continue construction up a column or wall and should be removed before casting continues. Also, flow channels of low cement content, and therefore low strength, can occur in the body of concrete structures. In reinforced concrete structures, this bleeding can cause voids beneath the reinforcement, which are reported to be sites for potential corrosion attack.<sup>22</sup>

### **3.30.3.2 The Second Stage**

The growth of plastic strength begins after the end of the dormant phase and can be divided into two stages. At the end of the dormant phase a period of hydration takes place, known as 'setting,' which lasts to about 30% of the total hydration. During this stage, the cement loses its plasticity and the cement paste becomes hard. Coagulation of the structure takes place and is characterized by the presence of a three-dimensional network formed by disordered coupling of the finest particles in the disperse phase through thin layers of the dispersion medium, resulting in a network low in strength. In this stage, crystallization only occurs in the form of individual crystallites, mainly in the form of calcium hydroxide and sulfoaluminate.

The onset of this phase is known as the initial set, and the end of the set, marked by the total loss of plasticity, is known as the final set.

### **3.30.3.3 The Third Stage**

After the final set, the hydration process slows down and the 'hardening period' begins, during which the cement gains most of its mechanical strength. In this stage, more intense crystal formation is accompanied by crystal bonding, forming a strong crystalline network. Subsequent strength development comes from the growth of hydrated calcium silicate crystalline structure as crystals are formed from the supersaturated solution. The rate of this stage is controlled by diffusion through the cement matrix. If mechanical deformation is applied at the onset of this stage, it is usually detrimental to its ultimate strength.

### **3.30.3.4 Admixed Chlorides and the Rate of Hydration**

Calcium chloride falls into the category of accelerating admixtures and, being a low-priced industrial by-product, was extensively used. In 1977, however, due to the increased risk of corrosion of reinforcement

steel, the use of chloride-based accelerators was prohibited in all reinforced or prestressed concrete in the United Kingdom.

Accelerators increase the initial rate of chemical reaction between the cement and the water so that the concrete stiffens, hardens, and develops strength more rapidly. This is a benefit because it allows the earlier striking (i.e., removal) of formwork. They have a negligible effect on workability and 28-day strengths are rarely affected. The addition of small amounts ( $<1$  mass%) of calcium chloride sometimes retards the set; however, this effect is very variable. Larger amounts produce an acceleration, and amounts over 3% have been known to cause a flash set. Sodium chloride produces a less pronounced change in the rate of hydration and the effect is more erratic, sometimes accelerating, sometimes retarding.

### 3.30.3.5 Summary of the Hydration of Cement

The hydration products of the silicates are basically a calcium silicate hydrate gel of varying morphology and composition between  $1 < C/S < 2$  and calcium hydroxide. Contained within this gel are areas where iron, sulfate, and aluminum ions have been adsorbed into the lattice. It is probable that some chlorides can also be absorbed in this way. Chlorides may also form complexes with hydrating calcium silicates. Specific information about the calcium silicate hydrates is hard to obtain because they are poorly crystalline, which leads to difficulty in analysis. Also, variations occur throughout the cement matrix, which are time dependant because of the nature of the solid solutions formed.

Aluminate hydrates also form solid solutions, leading to time-dependant variations as compounds migrate through the matrix. Chlorides are predominantly bound to the aluminate compounds by the formation of Friedel's salt. The hydration products of the aluminoferrites are similar to those of the aluminates with iron substituting for aluminum in varying quantities.

The hydration of cement takes place in three stages. A period of rapid hydration occurs as water is added to the anhydrous cement. After about 15 min this stops and a period of little activity takes place, known as the dormant period. This lasts for about 3–4 h, after which hydration recommences. The end of the dormant period is thought to be caused by the break down of some protective membrane of hydration products covering the surface of the cement

grains or by the transformation of a hydrate to a more porous form or by the volume of hydrates on the surface of the grain reaching a critical mass. The post dormant phase of hydration is known as the setting period, when crystallites of calcium hydroxide and sulfoaluminate are known to form. Eventually, the hydration products build up and this causes the process to become diffusion controlled. It is during this hardening period that the cement gains its mechanical strength.

### 3.30.4 High Alumina Cement

High alumina cement (HAC), as the name suggests, contains a large proportion of alumina; typically about 40% each of alumina and lime with around 15% of ferrous and ferric oxides, plus 5% silica.

HAC was developed as an alternative to OPC because of its increased resistance to sulfate attack, and in this respect, it performs well. This resistance to sulfate attack is due to the absence of  $\text{Ca}(\text{OH})_2$  in hydrated HAC and also due to the protective influence of the relatively inert alumina gel formed during hydration. HAC is not attacked by  $\text{CO}_2$  dissolved in pure water, and while it is not acid resisting, it can tolerate very dilute solutions of acids ( $\text{pH} > \sim 4$ ) found in industrial effluents but not hydrochloric, hydrofluoric, or nitric acids.

Another positive feature of HAC is its very high rate of strength development. About 80% of its ultimate strength is reached in 24 h, and even at 6–8 h the concrete is strong enough for the side formwork to be struck and for the preparation for further concreting to take place. It is for this attribute that it became popular for the production of precast beams used in floor and roofing systems in the late 1960s and early 1970s.

Because a number of high profile catastrophic failures occurred in the early 1970s, the suitability of HAC concrete for use in structural components has been of concern. The Building Research Establishment (BRE) subsequently carried out a major investigation<sup>23</sup> and identified that HAC is subject to a process known as conversion.

Conversion occurs due to the primary hydrates present in the material being chemically unstable. The conversion process involves a change in the mineralogy of the cement, which becomes increasingly porous and friable with age and also loses alkalinity. Under conditions where the overall dimensions of the body are constant, as is the case in set

cement paste, conversion results in an increase of porosity of the paste.

The strength of hydrated cement paste or of concrete is very strongly affected by its porosity; a porosity of just 5% can reduce the strength by more than 30%. As a result, conversion markedly reduces the strength of HAC. Also, the increased porosity means the concrete is more susceptible to other forms of attack such as alkali, sulfate attack, or carbonation.

As the concrete becomes more porous, it allows easier movement of oxygen and water as well as aggressive species like chloride ions. This, combined with the loss of alkalinity, can result in the increased possibility of reinforcement corrosion, which can also cause deterioration of the concrete. This deterioration is accelerated by the presence of excess water, for example, from leakages, condensation, or groundwater.

The effects of conversion on the strength of beams depend on the original strength and quality of concrete used. In some cases, the increase in porosity has been reported to allow moisture to react with unhydrated cement particles and produce an increase in strength. In other cases, significant strength reduction can take place.

### **3.30.5 Pozzolan Materials**

A number of materials are available that can be used to partly replace the cement content of a concrete mix, saving cement and usually providing additional benefits in terms of performance and durability; these include blast furnace slag, fly ash, metakaolin, and natural volcanic ashes. Such materials, whether natural or human-made, have been thermally modified to produce potentially reactive compounds of silica and alumina.

The first hydraulic cements based on pozzolanic materials date back to Roman times. These were materials that reacted with lime water to produce a hardened mass and employed the volcanic ash obtained from the slopes of Mount Vesuvius, in the vicinity of the Italian town of Pozzuoli from which the term Pozzolan originates. The term is now commonly used to represent any material that reacts with alkaline water to harden. There are a number of industrial by-products that are used in this way to replace a proportion of the cement used in concrete.

There are typically two main benefits. The first is a reduction in cost, as the by-products are typically cheaper than the cement they replace. The second

is a perceived enhancement in the properties of the concrete produced. This can take the form of increased resistance to aggressive materials, enhanced strength, or slower curing (which for large concrete pours is a benefit as the heat generated is reduced and consequently the risk of thermal-induced cracking when the concrete cools). There is a further potential benefit with regards to sustainability, as there is less cement used and it consumes what would otherwise be an industrial by-product.

#### **3.30.5.1 Ground Granulated Blast Furnace Slag**

Typically up to 70% of the cement used in a mix can be replaced with ground granulated blast furnace slag (GGBS). This means that a relatively standard concrete mix containing 300 kg of cement per cubic meter of concrete would contain 90 kg of OPC and 210 kg of GGBS. The benefits of GGBS are typically a reduced heat of hydration for large pours, and an increase in the overall durability of the concrete. This is both due to an increased resistance to the effects of aggressive chemicals on the concrete and due to a reduced rate of passage for aggressive species such as chlorides into the concrete.

The reduced heat of hydration produces a slower strength gain and a longer setting time. This means that the concrete may require more careful placement and curing techniques to minimize the risk of plastic cracking problems. The slower hydration may also produce substandard strength gain, resulting in a difficulty in achieving a target strength (the common method used to assess the quality control of concrete on a construction site). Some cases have been found where a portion the GGBS did not hydrate, but this is rare.

#### **3.30.5.2 Pulverized Fuel Ash**

Pulverized fuel ash or fly ash (PFA) is a by-product of coal-fired power stations and can achieve similar effects to GGBS, that is, an increase in durability and a reduction in heat of hydration, with a risk of plastic cracking problems because of difficult curing. The replacement quantities are lower than GGBS (typically up to 35%).

#### **3.30.5.3 Silica Fume**

Silica fume, also known as microsilica and nanosilica, is a highly reactive pozzolanic filler, which is used to achieve high strength and dense concrete. Silica

fume is a by-product of the manufacture of silicon and ferrosilicon alloys from high-purity quartz and coal in a submerged-arc electric furnace. The  $\text{SiO}_2$  content is generally in the range between 80 and 98 mass%. The process produces a very fine material, which has a high pozzolanic reactivity. The silica particles react with the calcium hydroxide of the cement paste and form calcium silicate hydrates. The hydrates fill the space between the cement hydration products, and in particular, the weaker calcium hydroxide interface around aggregate particles increases the strength and density of the concrete. Contrary to the other cement replacements, the use of silica fume leads to a more rapid hydration and typically higher strengths.

#### 3.30.5.4 Inert Fillers

Fillers are very finely ground materials, which have a similar particle size to Portland cement. Fillers, such as limestone or quartz powder, are inert or quasiinert materials, which mainly improve the density and stability of the cement paste. The workability, permeability, bleeding, or cracking tendency are also improved. Inert fillers do not contribute to the hydration; however, limestone powder can be beneficial for the hydration. It is able to form monoaluminate carbonate hydrates and supports the formation of ettringite.<sup>24</sup>

Modern UK and European Portland cements (CEM I), BS EN 197-1:2004, are permitted to contain up to 5% limestone filler as a minor addition. This can lead to a higher susceptibility to thaumasite formation because of a considerable internal source of carbonate ions.<sup>25</sup>

### 3.30.6 Concrete

Concrete has been an important construction material for more than the last 100 years. Concrete is a three-phase system consisting of cement, aggregate, and water. Nowadays, concrete is usually a five-phase system because of the addition of additives and admixtures for property improvements and cost reduction. The binder compounds cement and additives are discussed in [Sections 3.30.1.1](#) and [3.30.5](#), respectively.

#### 3.30.6.1 Aggregate

Aggregates occupy more than 75% of the volume of concrete and hence form one main indicator of

the strength. The properties of aggregate characterize the performance of concrete. According to the density of aggregate, concrete is divided into three groups of lightweight ( $400 < 2000 \text{ kg m}^{-3}$ ), normal ( $2000\text{--}2800 \text{ kg m}^{-3}$ ), and heavyweight concrete ( $\geq 2800 \text{ kg m}^{-3}$ ).

Aggregate is a cheap compound in relation to cement. Hence, it is desired to use as much aggregate as possible, but with the restriction to achieve a durable concrete. Aggregate influences physical, chemical, and thermal characteristics and may affect the durability. Beside the economic factors, aggregate is used to increase the concrete's stability, that is, reduction of shrinkage, to decrease the susceptibility to chemical attack due to the reduction of susceptible cement paste, and to decrease thermal effects. Cement paste is susceptible to shrinkage-induced cracking, carbonation, sulfate attack, and mechanical attack such as erosion and fire. However, aggregate can cause concrete deterioration such as alkali-silica reaction, frost attack, and in the case of salt contamination, corrosion may be initiated. Organic impurities may affect the hydration, and coating of fine particles such as clay may reduce the bond.

To obtain good quality concrete, the compactness of the aggregate bulk has to be high, that is, to follow certain particle size distributions. This is mainly achieved using at least two size groups: fine (0–5 mm) and coarse (>5 mm) particles. The fine particles are also referred to as sand.

Another point of division of aggregate is based on their source. There are natural and industrial manufactured aggregates. Industrial products are mainly light- and heavyweight aggregates. Examples of natural aggregates are basalt, granite, limestone, quartz, and gabbro.

The strength of natural occurring aggregates is mostly higher than the cement paste; therefore, the weakest part within the concrete system is the cement paste, and in particular, the interface between cement paste and aggregate. The strength of cement correlates well with the concrete strength of a three-phase system. On the other hand, lightweight aggregates have a lower strength than do the cement paste. There are three different crack patterns that relate to the strength relation between aggregate and cement paste in concrete. Concrete under stress may crack either within the cement paste or along the aggregate-paste interface or through the cement paste and aggregate particle or within the aggregate materials.

### 3.30.6.2 Water

Water is the third main phase within the concrete system, beside cement and aggregates. Water is essential for the formation of the strength giving hydrates within the cement paste such as the C–S–H phases. Hydration of cement is discussed in [Section 3.30.3](#). The effects of the quantity of water, the water–cement ratio, on the strength are discussed in [Section 3.30.6.5](#).

Natural occurring water and recycled water from concrete production can be used. The suitability depends on secondary substances in the water. Impurities may affect the hydration and consequently the strength of concrete. Organic substances should not be present. Seawater should not be used in reinforced concrete. The use of recycled water is specified in EN 1008. The usable amount of recycled water depends on the actual density showing the percentage of fine particles. Recycled water should not be used in concrete with air entrainment.

### 3.30.6.3 Admixtures

Admixtures are an additional ingredient of concrete. They are used to improve fresh concrete properties, such as workability and bleeding behavior, combined with an increase in strength and durability.

BS EN 934-2:2001 defines admixtures as “materials which are added during the mixing process of concrete in a quantity not more than 5% by mass of the cement content of the concrete, to modify the properties of the mix in the fresh and/or hardened state.” They are mainly based on chemicals. Admixtures can be classified according to their function in

- water reducing/plasticizing,
- high range water reducing/superplasticizing,
- water retaining,
- air entraining,
- set accelerating,
- hardening accelerating,
- set retarding,
- water resisting,
- set retarding/water reducing/plasticizing,
- set retarding/high range water reducing/superplasticizing, and
- set accelerating/water reducing/plasticizing admixture.

The application of admixtures should always be in accordance to the manufacturers' guidance. The dosages should be within the recommended range

because of the high sensitivity of concrete to the admixture.

Plasticizers are used to reduce the water–cement ratio in order to gain early and high-strength concrete with increased durability. Air entraining admixtures are used to increase the freeze–thaw resistance. Accelerating admixtures are commonly used in the precast sector and for cold weather concreting, whereas retarding admixtures are used to counteract the effects of hot weather on hydration.

Admixtures are a relative expensive component of concrete, however, the positive effects, such as increased workability and durability, can reduce total costs.

### 3.30.6.4 Concreting

Concrete should be mixed so that a homogenous mix is ready for transport and placement. The time between first contact of cement and water and final placing is limited to 90 min. The temperature of the concrete when placed is also limited so that the concrete temperature should be in the range of 5–30 °C. Concreting should be suspended when the air temperature is 3 °C and falling. The temperature of concrete placed in hot weather conditions can be reduced using cooled aggregates, ice as water replacement, or special curing methods to prevent excessive core and surface temperatures.

The placed concrete should be properly vibrated so that the reinforcement is enclosed and air voids (<1 mm) are reduced to less than 2%. However, over-vibration may cause loss of homogeneity because of segregation. The following curing process mainly determines the durability of the concrete. This is of special importance during cold and hot weather concreting. Concrete placed in cold weather should be cured longer to allow for the retardation of the hydration. The temperature gradient between core and surface should be minimized and the concrete should be prevented from freezing during its early stages of hydration. All surfaces should be protected against any weather effects. The rate of hydration increases with increasing temperatures so that special curing measures have to be taken into account in hot weather conditions. These may be cooling systems within the core of the concrete to prevent temperature above 60 °C, protection of the surface against sun, wind, and evaporation, and continuous humidification to achieve high grades of hydration within the surface layer.

Improper curing in cold weather may cause excessive bleeding, increased pore volume due to freezing, plastic cracking and thermal cracking caused by high temperature gradients. Wind and sun may cause extensive surface evaporation, causing a highly porous, less durable surface. Excessive core temperature can cause cracking and thermodynamical changes within the hydration products, causing delayed ettringite formation (DEF).

### 3.30.6.5 Strength of Concrete

The compressive strength of concrete is the most expressive property to describe the quality, and therefore, the long-term performance of concrete. This characteristic mainly determines the durability and permeability and can primarily be described with the water–cement ratio ( $w/c$  ratio). Secondary parameters affecting the concrete strength are aggregate–cement ratio, the properties of the aggregate, including the maximum aggregate size and the degree of compaction. In addition to the strength of concrete, the curing regime is of significant importance to achieve a durable and long-performing concrete structure.

The water–cement ratio is inversely proportional to the strength under the condition that the concrete is well compacted, allowing an air void content of less than 2%. The inverse proportionality is not valid below a  $w/c$  ratio of 0.38. The amount of water required for the total theoretical hydration of cement is in the range of 0.26–0.28; however, water is also physically bound within the cement matrix, that is, water is absorbed. A  $w/c$  ratio of 0.38 is required for the total hydration, including chemical and physical bond. Below this value, the degree of hydration and compaction decrease causing loss of strength. The increase of the  $w/c$  ratio above 0.38 causes the formation of capillarity pores, and hence, a reduction in strength. Water–cement ratios commonly used in the field are in the range of 0.45–0.60 or admixtures are added to achieve workability by low  $w/c$  ratios.

The effective water–cement ratio available for the hydration varies to the amount of water added to the mix. Additional water may be supplied by surface moisture of aggregate or water may be withdrawn from the mix because of absorption from the not saturated aggregates.

Various types of pores are present in the hydrated cement matrix, which may affect strength and durability. Gel and shrinkage pores formed during the hydration of cement are a usual compound within

the matrix. Capillary pores form above  $w/c = 0.38$  by total hydration; however, these pores may form below this value by reduced degree of hydration. The capillary pores are responsible for all transport processes within the concrete. Continuity between the capillary pores should be prevented until a  $w/c$  ratio of  $\sim 0.45$ , providing a durable concrete. Air voids formed during the mixing process can have a diameter up to 1 mm. To improve the freeze–thaw resistance artificial air pores can be introduced by using an air entrainment admixture. These pores are round and not connected and have a maximum diameter of 300  $\mu\text{m}$  to allow the freezing water to expand. The last type of porosity is due to compaction voids, which mainly arise from variable workmanship.

The amount of cement within the mix can affect the strength. Very low cement contents and cement contents exceeding about 530  $\text{kg m}^{-3}$  decrease the performance. High cement contents may cause extensive hydration shrinkage leading to large cracks in the paste. The properties of the aggregates are another secondary parameter, as partly discussed in [Section 3.30.6.1](#). Beside the type of aggregate, the moisture, surface texture, grading, and strength influence the strength of concrete.

Concretes are classified in EN 206-1:2000 according to their compressive strength after 28 days, see [Table 2](#). The classification for lightweight concrete is similar and can be found in EN 206-1:2000.

**Table 2** Standard concrete strengths according to EN 206-1:2000

Concrete compressive strength class	Minimum characteristic cylinder strength $f_{ck,cyl} (\text{N mm}^{-2})$	Minimum characteristic cube strength $f_{ck,cube} (\text{N mm}^{-2})$
C8/10	8	10
C12/15	12	15
C16/20	16	20
C20/25	20	25
C25/30	25	30
C30/37	30	37
C35/45	35	45
C40/50	40	50
C45/55	45	55
C50/60	50	60
C55/67	55	67
C60/75	60	75
C70/85	70	85
C80/95	80	95
C90/105	90	105
C100/115	100	115

### 3.30.7 Degradation

#### 3.30.7.1 Cracking

There are many different types of crack that can occur in concrete. The consequences of these can range from purely aesthetic to structurally significant, and care should be taken when assessing them. It should always be borne in mind that concrete will always typically crack, but that cracks may or may not be structurally significant. Cracks may be as a result of the manner in which it performs structurally, as concrete has a low tensile strength. These are discussed in the order they occur, in the following sections.

##### 3.30.7.1.1 Plastic settlement cracking

During concrete hydration, there is a period where it is a solid suspended in a liquid phase. This is known as the plastic stage. If this stage lasts too long, or the mix contains a significant amount of water, the solid particles can settle, see [Figure 1](#). Mixes that hydrate slowly, such as those placed in cold weather, or with a high proportion of cement replacements are typically more vulnerable to this type of cracking. This typically manifests itself in the form of cracks immediately over the reinforcement steel, which provides a shorter path for the ingress of potentially aggressive species. If plastic settlement cracks are visible on a new structure, there is a significant possibility that extensive cracking has occurred and the surface should be grit blasted to identify the true extent of the problem before remedial measures are considered.

##### 3.30.7.1.2 Plastic shrinkage cracking

If during hydration water is lost to the atmosphere quicker than it can be replenished from the hydrating

concrete, the surface undergoes plastic shrinkage cracking. This typically takes the form of many small cracks over the surface of the structure and can be minimized with careful curing. As with plastic settlement cracking, if this is visible on the surface of concrete, the true extent needs to be identified before embarking on remedial measures. This can be achieved by a light grit blast.

##### 3.30.7.1.3 Early age thermal cracking

As concrete hydrates, it generates heat. If this heat is not adequately controlled, then the concrete will cool after hydration, and as a result, will shrink. This may result in visible cracks forming. For water retaining structures, the basic approach is to limit the width of cracks by having a higher number of smaller cracks.

##### 3.30.7.1.4 Long-term drying shrinkage

Over a significant period of time, concrete tends to shrink as shown in [Figure 2](#). This will produce cracks and can be the basis or the allowable movement at structural joints. If the movement does not occur at the joints, there is additional restraint or the joints are incapable of movement, shrinkage cracks may occur. These are typically uniformly spaced across a structure as the concrete tends to shrink in a uniform manner.

#### 3.30.7.2 Corrosion of Steel in Concrete

The single commonest cause of degradation of reinforced concrete is corrosion of the reinforcement. The pore water in concrete is highly alkaline and in a strongly alkaline environment steel is passivated, and does not corrode, by the formation of a stable and adherent oxide coating, thought to be  $\text{Fe}_2\text{O}_3$ . However,

**Figure 1** Plastic settlement cracking.

**Figure 2** Shrinkage.

this passive film can become unstable due to two mechanisms: those of chloride ion attack and carbonation. This is instigated by either carbon dioxide penetration reducing the pH, or by the presence of chlorides. Once corrosion has initiated, the rust produced is typically insoluble and has a greater volume than the original steel. As a result, tensile stresses develop in the concrete and the cover delaminates. This typically occurs with section losses below that, which are structurally sensitive; however, the falling concrete can pose a significant hazard. In addition, the corrosion may be taking place in an unobservable area, and hence the damage may go unnoticed until significant corrosion has taken place. In addition, the original design may have a limited factor of safety by current standards, and hence any corrosion may be intolerable.

#### 3.30.7.2.1 Chloride attack

Chloride ions are considered to be the major cause of corrosion of reinforcement, see [Figure 3](#). The level at which chlorides are generally considered to represent a risk of corrosion is typically greater than 0.4 mass% of cement.

#### 3.30.7.2.2 Sources of chloride ions

The main source of chloride ions is typically from external sources such as deicing salts on roads or from the marine environments, the sea. However, there are situations whereby chlorides can end up in the concrete mix prior to casting of the concrete. Chlorides from this source are known as internal chlorides, and during the hydration of cement, a quantity of these are bound to the cement hydrates. For any particular cement, the relationship is thought to be primarily governed by the ratio of chloride to cement by mass. Internal sources can be from aggregate contamination by using marine-dredged

aggregates that have not been washed properly, or by using contaminated water in the mix. Note that in some parts of the world, it is difficult to obtain chloride-free aggregates and chloride-free water. Chlorides have been deliberately added to the mix to control the hydration rate, although this practice has been discouraged.

#### 3.30.7.2.3 Carbonation

Carbonation occurs where carbon dioxide in the atmosphere dissolves in water to form carbonic acid. This reacts with the alkaline concrete and reduces the pH to a value below 10, see [Figure 4](#). It has been reported<sup>26</sup> that carbonation also increases the concentration of free chloride in the pore solution by releasing bound chlorides.

As the above processes require some diffusion through the concrete to the steel any factor that influences the rate of these processes also affects the corrosion rate, thus dense well compacted concrete with adequate cover can provide excellent protection to embedded steel and there are oil platforms in the North Sea that have survived 17 years<sup>27</sup> with no observable corrosion of the reinforcement bars taking place. Cement replacements are often used to provide an enhanced durability and resistance to passage of aggressive ions but do require more care in placement or these benefits may not be realized.

#### 3.30.7.2.4 Chloride ion diffusion

As stated above, chloride ion ingress is the major cause of deterioration of reinforced concrete structures. Therefore, knowledge of the nature of diffusion of chloride ions through concrete would be necessary for any structure to have a designed lifetime. Ideally,

**Figure 3** Chloride-induced corrosion.

**Figure 4** Carbonated concrete sample treated with phenolphthalein indicator (magenta color represents uncarbonated concrete).

it would be possible to calculate a figure for the time taken for chlorides to reach the steel in sufficient quantities to cause depassivation from the mix design and cover. This has led to certain experimental procedures being developed that attempt to model chloride diffusion on a laboratory scale and these methods are outlined below.

Generally, current investigations into this topic can be divided into three types: those using the diffusion cell method, those using immersion into solution, and those using electrical properties of concrete to monitor diffusion, usually resistivity. The first two methods apply laws developed by Adolf Fick in 1858, which govern diffusion on a quantitative basis, to obtain diffusion coefficients for the materials under test; the third infers a diffusion coefficient from the change in the total quantity of ions in the pore solution with time, which manifests itself by an increase in ionic conductivity.

### 3.30.7.2.5 The diffusion cell

In this type of experiment, slices of cement mortar are taken and inserted into a diffusion cell.<sup>28</sup> Both sides of the cell are filled with either deionized water, saturated calcium hydroxide, or dilute sodium hydroxide, with one side containing chloride ions added in the form of sodium chloride. This method applies Fick's first law after the rate of change of chloride ion concentration in compartment one becomes constant:

$$-\mathcal{J}(x) = \frac{dC}{dt} = D_c \frac{dC(x)}{dx}$$

where  $\mathcal{J}(x)$  is the flux of  $x$ ,  $D_c$  is the diffusion coefficient ( $\text{m}^2 \text{s}^{-1}$ ), and  $C$  is the concentration.

Tests such as this can take a significant length of time to achieve steady state. To avoid this, a direct current voltage can be applied to accelerate the test and calculate the flux of ions from the total current flowing. The problems with this method are that current is used in transporting all ions, not just the chlorides, and also a certain amount of heat is developed.

A modified version of this test was used by Luping and Nilsson,<sup>29</sup> who applied the test to both cement paste and mortar samples of varying water–cement ratios and applied a voltage of 30 V across a 70-mm-long cured samples with solutions of saturated calcium hydroxide and 3% sodium chloride. They compared the results obtained in this manner with conventional diffusion cell data and recorded current and temperature (a rise of only a few degrees after 8 h

of testing) and obtained chloride profiles by sectioning the samples after 2 months of testing. The following equation was produced as a method of calculating the diffusion coefficient from the depth of chloride penetration, derived from a combination of electrochemical and ionic diffusion equations.

$$D_c = 1.189 \times 10^{-11} \frac{X_d - 1.061 X_d^{0.589}}{t}$$

where  $D_c$  is the diffusion coefficient ( $\text{m}^2 \text{s}^{-1}$ ),  $X_d$  is the depth of chloride penetration (m), and  $t$  is the time (s).

This suggests a clearly defined depth of chloride penetration, which is not necessarily the case. As an alternative, Fick's second law can be applied to calculate the diffusion coefficient under non-steady-state conditions.

$$\frac{\delta C}{\delta t} = D_c \frac{\delta^2 C}{\delta x^2}$$

where  $D_c$  is the effective diffusion coefficient ( $\text{m}^2 \text{s}^{-1}$ ).

### 3.30.7.2.6 Immersion testing

As the name suggests, in this type of diffusion, testing blocks of concrete are taken, all but one of their surfaces are sealed, and the blocks are immersed in a solution. After a time, the blocks are removed and chloride ion profiles are obtained. Sections of the block are taken using either dry drilling or cutting with a diamond saw. The solutions in which the samples are immersed vary considerably from sodium chloride to seawater. For unidirectional diffusion into a semiinfinite medium, an accepted solution to Fick's second law is:

$$C_{(x,t)} = C_o \left( 1 - \operatorname{erf} \frac{x}{2\sqrt{D_c t}} \right)$$

Where  $\operatorname{erf}(z) = \frac{2}{\sqrt{\pi}} \int_0^z e^{-y^2} dy$ ,  $x$  is the distance from the exposed face (m),  $C_o$  is the surface concentration, and  $t$  is the time (s).

### 3.30.7.2.7 Resistivity measurements

Although not a direct method of measuring diffusivity of ions into concrete, this technique has been applied to infer variations in ionic concentrations in the pore solution. The use of conductivity in concrete as a measure of diffusivity was first suggested by Brace<sup>30</sup> for use in analyzing the properties of rocks. If a material is made up of a solid, insulating phase, with a

liquid phase distributed through it, then diffusion and conductivity are controlled by the same process and are related using the Einstein relationship.

$$\sigma = \frac{e^2}{kT} \sum_j c_j Z_j D_j$$

where  $\sigma$  is the conductivity ( $\Omega^{-1} \text{ m}^{-1}$ ),  $e$  is the electron charge,  $k$  is the Boltzmann constant,  $T$  is the absolute temperature (K),  $c_j$  is the number of ions per unit volume of  $j$ ,  $Z_j$  is the valency of  $j$ , and  $D_j$  is the diffusion coefficient of  $j$ .

Buenfeld and Newman<sup>31</sup> continued this work, on the basis that the conductivity of concrete when wet is  $5 \times 10^8$  times more than that of the dry material, and therefore electrical conductance takes place through the pore water. They point out, however, that the conductance depends entirely on the composition of the pore water solution, and therefore, variations in conductivity could be due to any increase in any ions in the pore solution, or the variations could be due to surface changes in the concrete itself.

### 3.30.7.2.8 Errors in diffusion experiments

The fundamental purpose of the above experiments is to obtain a value characteristic of the rate of ionic movement of chlorides through concrete. Ideally, it would be then possible to take this figure and apply it in the design stages of a structure to provide an accurate life expectancy.

This approach is flawed for concrete structures as design lives are very long, 120 years for bridges, and over this period of time, the environment can change considerably; for example, consider how much the world has developed over the past 120 years. With design lives of this scale the problem becomes one of adequate maintenance and repair rather than an initial design and build problem, although, of course, the ability to maintain the structure must be designed for.

Accelerated testing for diffusion involves either using thin sections or applying a voltage across the samples to accelerate the ionic flux. The first method must be questioned, because if used as an accelerated test, it may miss important effects that occur later in the life of the sample, as the morphology of the pore structure changes on contact with the solution. The second is additionally unsafe, because in concrete, charge balance is maintained as chloride ions diffuse in by the migration of hydroxide ions (see later). This would not be the case if using an applied voltage, and

therefore, too much emphasis may be placed on the diffusion of cations in the process.

Chatterji<sup>32</sup> states that the assumption of constant diffusivity is seldom satisfied, with results suggesting that an increasing or decreasing depth of penetration could be observed depending on history. He adds that the use of a measured diffusion coefficient by any method to calculate the long-term chloride penetration depth is uncalled for and may be misleading.

Theoretically, Fick's second law cannot be used to analyze the chloride ion migration data through cementitious materials, as no account is made for any chemical reactions that take place during the process. Saetta *et al.*<sup>33</sup> reported that temperature, relative humidity, and degree of hydration all have an effect on the effective diffusion coefficients.

### 3.30.7.2.9 Corrosion ladder

This is a proprietary corrosion sensor developed by Raupach *et al.*<sup>34</sup> to allow monitoring of the indication of potential corrosion problems in new structures. Steel bars are cast parallel to the reinforcement at varying depths from the concrete surface up to and beyond the depth of rebar at strategic places in the structure. The potentials of these are recorded and when they change from a passive state to an active one, it is an indication that the steel has depassivated either due to the presence of chlorides or by carbonation. The occurrence of corrosion can be checked by connecting the mild steel electrodes to the stainless steel. If the mild steel has depassivated, then a current will flow, which can be measured using a zero resistance ammeter.

One possible problem with this method of monitoring is that when the chlorides reach the steel, it starts to corrode, producing voluminous corrosion products, and hence causes the concrete to spall. It is possible that only a small area of the steel has enough chlorides to cause activation and this test may therefore be unrepresentative of the overall state of the structure. In addition to this, very accurate positioning of the steel would be required in a small distance of concrete not greater than 150 mm. The size of the probe may also cause difficulties in areas of high stress, where the presence of the probe may reduce the load-bearing capacity of the section.

### 3.30.7.2.10 Tests on retrieved samples

The following testing methods all involve taking a sample of concrete. This is done by collecting the dust from a drilled hole and treating this with nitric acid to extract the free and bound chlorides into

solution. This solution is then usually neutralized and a known quantity is taken for testing by an external laboratory. The locations for testing are invariably limited by available time and access, and therefore, care must be taken in assessing the results.

### 3.30.7.2.11 Chloride ion selective electrodes

As the potential of the silver–silver chloride electrode depends on the chloride ion activity, the temperature, and the standard electrode potential of both the ion selective electrode and the reference electrode (it is compared with), in laboratory tests, the chloride-sensitive electrode is first calibrated in a set of solutions of known concentration. When a plot of potential against the log of chloride concentration is made, a straight line is obtained, and therefore, when the ion-selective electrode is submerged into an unknown solution, the chloride concentration of the solution can easily be calculated from the calibration plot. The potential obtained can be affected by the presence of bromide ions from a marine environment as there is some bromide in seawater. This approach has been used to produce a commercially available probe that has been installed in a number of structures.

### 3.30.7.3 Alkali-Silica Reaction

Alkali silica reaction (ASR) is a type of the more known ‘Alkali-aggregate reaction’ and was first reported in the United States by T.A. Stanton in 1940.<sup>35</sup> The reaction between alkali and aggregate as the cause of concrete degradation has been investigated since the early 1920s due to the occurrence of ASR in a dam in California, where opal was used as aggregate. Europe and the United Kingdom generally assumed that ASR was a degradation process which only occurred in North America until first cases were discovered in the early 1970s. Nowadays, ASR is present and recognized throughout the world. The causes of ASR and the protective measures to minimize the risk are well documented.

ASR is a chemical reaction between various forms of silica from the aggregate and alkali hydroxides (NaOH, KOH) from the pore solution in presence of moisture. The alkalis mainly derive from the cement. The reaction product, the alkali–silica gel, is more voluminous than the concrete and, after exceeding the tensile strength of the concrete, forms a distinctive crack pattern, see **Figure 5**. The cracks formed have the appearance of a spider web; however, affected prestressed elements tend to show cracks parallel to the stress direction.

**Figure 5** Typical crack pattern of ASR.

The reaction affects the appearance and serviceability of a structure, although generally its structural integrity, particularly the compressive strength, is not affected. However, the formation of cracks can enhance the penetration of various aggressive compounds, leading to acceleration of other types of degradation. ASR is often observed in combination with corrosion and sulfate attack and can be their predecessor.

The reaction can be described in accordance to Wieker *et al.*<sup>36</sup> as follows.

Formation of alkali hydroxides (NaOH, KOH) during cement hydration

Water intake and expansion

The reaction can proceed when further water ingress takes place. The gel, an alkali–silica hydrate, is able to react with water and calcium hydroxide to form calcium silicate hydrates and alkali hydroxides, which can form more gel and degrade concrete over a long term.

This reaction is a definite process because the majority of the alkalis remain in the gel.

The formation of the alkali–silica gel causes swelling<sup>37</sup> and the expansion pressure developed during this process can reach up to  $20 \text{ N mm}^{-2}$ , exceeding the tensile strength of concrete, which is in the range  $2\text{--}5 \text{ N mm}^{-2}$ .

The reactivity of aggregate depends on the mineralogical structure of the  $\text{SiO}_2$  and its proportion of amorphous and other reactive forms of silica. The reaction between  $\text{SiO}_2$  and alkalis always occurs; however, this reaction is destructive in the presence of reactive  $\text{SiO}_2$ . All amorphous and cryptocrystalline  $\text{SiO}_2$  minerals can be considered as reactive.<sup>24</sup> These include opal, chalcedony, greywacke, granite, and porphyry. ASR can be prevented when one of the three risk factors, alkalis, reactive  $\text{SiO}_2$ , and moisture, is minimized or eliminated. Moisture cannot be entirely controlled. The use of reactive aggregates is difficult to exclude because of the regional availability of aggregate. The transportation of nonreactive aggregates is commercially inefficient.

The amount of available alkalis can be controlled during the manufacture of cement so that the  $\text{Na}_2\text{O}$ -equivalent ( $\bar{N}$ ) is less than 0.6,<sup>38</sup> which conforms to a hydroxide ion concentration of around  $500 \text{ mmol l}^{-1}$ . The use of GGBS, PFA, microsilica, or other pozzolanic material increases this threshold. Alkalis react with the high reactive fine pozzolanic particles during the early stages of the cement hydration before setting.  $\text{Ca}^{2+}$  ions are bound in reaction products of the pozzolanic material. These two reactions bind the alkalis in insoluble compounds with the cement matrix. Pozzolanas increase the density of the concrete, and hence, reduce the permeability of external and mobility of internal alkalis.

In the case of confirmed ASR degradation in structural elements, there are series of measures to monitor and control ASR. The IStructE<sup>39</sup> described these measures as follows:

- Regular monitoring of the structure to check that deterioration does not reach dangerous proportions. This requires experienced engineering judgment.
- Detailed check on the structural details to establish criticality, in particular, a critical examination of the robustness of the reinforcement detailing.
- Measures to reduce the amount of water available to the structure.
- Limited strengthening of the structure.
- Partial or full demolition followed by rebuilding.

The appropriate measure should be assessed through a series of investigations comprising the documentation of the degradation, a desk study to gain information about the materials used, the type of construction, and the rate of degradation. Destructive investigations should include the retrieval of cores in degraded and sound areas and their assessment in the

laboratory. This may include strength tests, petrographic examination, and visual inspection.

### 3.30.7.4 Sulfate Attack

#### 3.30.7.4.1 Conventional sulfate attack

The damaging influence of sulfates on concrete has been known since 1877, and first investigations were performed by Candlot<sup>40</sup> and Michaelis<sup>41</sup> at the end of the nineteenth century. They identified a complex water-enriched compound in the damaged matrix and described it as

Michaelis called the salt formed ‘cement bacillus,’ and nowadays it is known as ‘ettringite,’ and this is the main reaction product in various forms of sulfate attack. Several forms of sulfate attack have been identified that affect various phases of the cement hydration products.<sup>42</sup>

Sulfate attack can result in one of two forms of deterioration, the first is due to leaching of the calcium containing phases, particularly portlandite [ $\text{Ca}(\text{OH})_2$ ] as shown in Figure 6. The second is the more familiar expansive form caused by formation of more voluminous reaction products such as gypsum, monosulfate, and ettringite. The expansive form can

Figure 6 External sulfate attack.

be categorized by the location of the supplied sulfate whether there is an external or internal source.

The main reaction products of sulfate attack are gypsum and/or ettringite, and the reaction mechanism is generally accepted as portlandite transforms into gypsum and calcium aluminate hydrate into ettringite, the latter being the more expansive reaction. These findings allowed the development of sulfate-resisting Portland cement (SRPC-BS 4027-1996), which is mainly characterized by a limited tricalcium aluminate content ( $C_3A < 3.5\%$ ). The low presence of the main ingredient for the deteriorative reaction hinders the formation of the more voluminous reaction products, which is mainly ettringite. Guidelines, such as BS EN 206, BS EN 1992, and BS 8500, have also been produced resulting in the solution to the majority of problems caused by sulfate attack.

#### **3.30.7.4.2 Thaumassite form of sulfate attack**

The thaumasite form of sulfate attack differs to the forms described earlier, including the conventional sulfate attack in that the calcium silicate hydrates (C-S-H phases), the main binding agent in all Portland cement binders, is targeted rather than the calcium aluminate hydrates (C-A-H phases) and the highly soluble calcium hydroxide ( $Ca(OH)_2$ ).

Although TSA has been recognized for many years, it did not receive any serious attention from either industry or the research community until the discovery of 10 cases of the thaumasite form of sulfate attack in the foundations of overbridges along the M5 motorway in Gloucestershire in 1998.<sup>43</sup> The seriously attacked columns had been all buried in backfilled Lower Lias Clay and were discovered during strengthening works. In response to this discovery, the UK Government convened the Thaumassite Expert Group (TEG) with “the remit to produce interim advice and guidance on the implications for existing buildings and structures and for the design and specification of new constructions in the UK.”

The TEG emphasized that deterioration as a result of the formation of thaumasite has become a separate form of sulfate attack, which has the potential to affect a wide variety of components and a range of building materials. The TEG gave thaumasite two classifications. The first being the ‘thaumasite form of sulphate attack’ (TSA) where significant damage of the concrete–mortar matrix has occurred as a consequence of replacement of cement hydrates

by thaumasite. In this case, the TSA-affected concrete transforms into a soft, mushy mass with a distinctive white coloration. The second classification the ‘thaumasite formation’ (TF) refers to the occurrence of thaumasite as precipitations in pre-existing voids and cracks without causing deterioration of the host concrete or mortar. However, thaumasite formation can be a precursor of the thaumasite form of sulfate attack and constitute an early stage in the deterioration process, as suggested by Sims and Huntley,<sup>44</sup> who suggested changing the term TF to ‘incipient TSA’.

In their report, the TEG recognized two sets of conditions for the formation of TSA in buried concretes, these are four primary and four secondary risk factors. The TEG emphasizes “that all of the four primary risk factors need to be present before significant TSA will occur within a buried Portland cement-based concrete.” The primary risk factors are defined as

- a source of sulfates and/or sulfides in the ground;
- a source of carbonate;
- presence of mobile groundwater; and
- low temperatures ( $<15^\circ\text{C}$ ).

The source of silicate, which is also a necessary component, was not included into the risk factors as it is an actual element in all Portland cement-based materials and is mainly present as calcium silicate hydrate phases (C-S-H phases).

The four secondary risk factors are identified by the TEG as

- type and quantity of cement used in concrete;
- quality of concrete mix, compaction;
- changes to ground chemistry and water regime resulting from construction; and
- type, depth and geometry of buried concrete.

On the basis of the findings of the TEG and other researchers, conventional sulfate attack and thaumasite form of sulfate attack have to be considered as two separate forms, which occur in different environments. TSA takes mainly place in low temperatures ( $<15^\circ\text{C}$ ), whereas conventional sulfate attack is predominantly at ambient temperatures of  $>15^\circ\text{C}$ . However,  $15^\circ\text{C}$  cannot be considered as a threshold between both types of attack.

Low temperatures favor the formation of thaumasite where generally less than  $15^\circ\text{C}$  is necessary with an optimum value of  $\sim 5^\circ\text{C}$ . The formation ability increases with the decrease of the temperature, that

is, the lower the temperature the faster the formation of thaumasite.

One reason for the increase in deterioration rate with reduced temperature is solubility. The solubility of carbon dioxide increases with decreasing temperature, leading to about twice the amount of dissolved carbonate in solution at 0 °C than at 25 °C; portlandite is also more soluble at low temperatures, whereas thaumasite is in the order of a hundred times less soluble. From this follows an increased rate of deterioration at low temperatures.<sup>45</sup> On the other hand, lower temperatures lead to a better stability of the six-coordinated  $[\text{Si}(\text{OH})_6]^{2-}$  groups that are present in the structure of thaumasite. The cut-off point where the mineral formed changes from thaumasite to ettringite should be between 15 and 20 °C. The typical temperature conditions in the ground at foundation depth in the United Kingdom range from about 9 to 12 °C and are therefore in the optimum range of below 15 °C.<sup>46</sup>

The more frequent detection of TSA during the past decade is most probably due to the development of more selective analytical and diagnostic techniques, which are able to differentiate unambiguously between ettringite and thaumasite as well as mixed crystals of both. Crammond<sup>47</sup> suggests that TSA is not a recent phenomenon and has occurred likely in the past, but has not been recognized as such because of several reasons:

- failure to detect thaumasite in standard sulfate resistance tests;
- improved analytical techniques;
- buried concretes rarely inspected;
- postconstruction enhancement of sulfate levels in the ground; and
- changes in the composition of modern cements.

Many other cases of TSA may remain unidentified or have been reported spuriously as 'sulfate attack' caused by ettringite formation because of misidentification due to the structural similarities. Furthermore, the traditional diagnosis 25 years ago was performed using chemical analysis alone, and this method is not able to distinguish between ettringite and thaumasite. Nowadays, the mechanisms of the different types of sulfate attack are well known and the facilities for an unambiguous identification are available.

#### 3.30.7.4.3 Delayed ettringite formation

Ettringite is a hydration product with two faces. The formation of ettringite during the first stage of

cement hydration controls the setting time of the paste. Ettringite formation is responsible for the workability of fresh concrete. Ettringite can be destructive when it forms in the hardened cement paste. This degradation process has been mainly observed in heat-treated elements with high strengths and high density exposed to external conditions; however, the formation can also occur in non-heat-treated elements.

The destructive ettringite formation was first observed in a structural element at the beginning of the twentieth century. Ettringite is common hydrate in concrete and the presence does not need to conclude that a deterioration process had occurred.

The effect of increased heat on young concrete can be the formation of delayed ettringite. Causes are heat treatment of concrete elements and extensive heat development in mass concrete or under hot external conditions. Heat treatment of concrete accelerates the hydration and strength gain, respectively, and enables the manufacturer shorter stripping off times for the elements. Hot weather conditions can cause DEF during mixing and hydration as well as in already hardened concrete.

Temperature influences the stability of monosulfate and ettringite. The increase in temperature decreases the stability of both monosulfate and ettringite; however, the rate of the decrease of ettringite is higher, that is, monosulfate is thermodynamically more stable above 90 °C. Alkalis in pore solution reduce this threshold to 50–60 °C.<sup>48</sup> These changes of the stability of ettringite lead to the formation of monosulfate, free available sulfates ( $\text{Na}_2\text{SO}_4$ ) in pore solution, and sulfates bound in the C–S–H phases above the critical temperature. Calcium silicate hydrates are able to bind sulfate ions during the hydration. Monosulfate becomes metastable when the temperature drops below the critical threshold.

If the concrete element is exposed to changeable weather conditions, that is, wet–dry cycles, then the sulfate ions in the pore solution and within the C–S–H phases react with the metastable monosulfate and  $\text{C}_3\text{AH}_6$  to form the more voluminous ettringite. This reaction can cause expansion and cracking within the cement paste. The volume of ettringite is eight times greater than  $\text{C}_3\text{A}$  and 2.3 times greater than monosulfate. Ettringite can also form in pores and is not destructive.

Pozzolanas, latent hydraulic material, and microsilica reduce the susceptibility of concrete to DEF. Heat-treated elements should undergo special procedures, such as initial storage before treatment,

controlled warming, constant heat control, controlled cooling, and an after treatment.

### 3.30.7.5 Mechanical Damage

#### 3.30.7.5.1 Abrasion/erosion

Abrasion or erosion can be defined as the wearing away of surfaces. It is commonly considered that it requires the action of a hard material on a softer one, but this is not the case. Over a significant period of time, a soft material can slowly wear away a harder one.

Concrete is no exception to this and will be subject to abrasion with time. Typically, it is a very slow process, unless it is subject to other mechanisms discussed later. For conventional reinforced concrete, the abrasion is likely to be of most of the concern if it results in an uneven surface for traffic, or if it significantly reduces cover to the reinforcement. Uneven surfaces often allow puddles of water to form, which can markedly accelerate the abrasion process, see [Figure 7](#). When water is trapped while being subject to wheel loading, a significant pressure is exerted in the horizontal plane. This can rapidly lead to undermining of the surrounding surfaces, or opening up of existing defects, leading to increasingly more widespread surface degradation.

#### 3.30.7.5.2 Cavitation

Cavitation occurs when liquids undergo a change in pressure to a point where the pressure in the liquid is below its vapor pressure. This produces bubbles in the liquid, which subsequently collapse and produce shockwaves. This can result in a very aggressive environment and extremely high rates of abrasion. This process is accepted as a mechanism that results in

coastal erosion whereby air pockets within water are forced into fissures. The continuing inflow of water results in the collapsing of pockets and a range of shock waves being produced that result in degradation.

#### 3.30.7.5.3 Frost

Frost damage is caused by a simple mechanism. Moisture within the concrete expands as it freezes, and as a result, tensile stresses form near to the surface. This can result in the surface crazing then scaling off, see [Figure 8](#). In areas vulnerable to frost, a common approach to controlling the risk of frost action is to include an air entraining admixture. There are a range of products available to achieve this. The use of an air entraining admixture produces a series of evenly dispersed discontinuous pores within the concrete that are relatively uniform in diameter, the majority of which are less than 0.3 mm. This provides two benefits. The first is that the surface absorbency is reduced, because the pores are discontinuous. The second is that they are able to absorb the stresses induced by frost, because the pores remain air filled, and hence, unsaturated.

#### 3.30.7.5.4 Exfoliation

Exfoliation is caused by a similar principle to frost, in that the pore structure becomes filled with a material that subsequently expands, see [Figure 8](#). In this case, it is a solution containing soluble salts. As the moisture dries out, the solution becomes more and more concentrated until ultimately the soluble salts recrystallize. The recrystallized salts may be greater in volume than the original solution, and therefore, tensile stresses are imparted into the concrete.

**Figure 7** Erosion of concrete by flowing water.

**Figure 8** Exfoliation of a seawater outfall.

It should be noted that the surface of concrete that is exposed to the solution may not be the one that suffers from exfoliation. If one face of a concrete surface is adjacent to a highly concentrated solution, and the other is exposed to a drying environment, the salt solution can be drawn a significant distance to the drying face, where the recrystallization takes place. This can be a problem in immersed tunnels. Typically, the solution on the exterior of the tunnel is chloride contaminated and the capillary absorption that takes place will cause corrosion as well as exfoliation.

The first thing to note is that concrete already contains a supersaturated solution of calcium hydroxide. However, calcium salts typically have a relatively low solubility, and therefore, as the moisture dries out, the salts that are precipitated do not have a large volume expansion associated with them. For exfoliation to occur, a more soluble salt is usually present. In many cases in natural environments, this is sodium chloride based, but any highly soluble salt can produce a similar effect.

Coatings or waterproofing for concrete are commonly vapor permeable to prevent osmotic blistering. As a result, this can cause a drying out of the coated concrete. If the concrete is contaminated with a soluble salt, the concentrations in the pores under the coating will increase, until the salts precipitate. This can cause the surface to exfoliate, which can result in coating failure. It should also be noted that solubilities typically increase with temperature. As a result, exfoliation may also occur due to a temperatures change.

To control the risk of exfoliation or frost attack, the basic approach is to either prevent significant salt ingress or prevent drying of the surface. Typically, a coating system would provide protection against salt ingress, but note that a vapor permeable coating can increase drying out of the concrete and may therefore cause exfoliation if the substrate is heavily contaminated.

### 3.30.7.5.5 Fire

Following the great fire of Chicago in 1871, all iron- and steel-framed structures were coated with a basic form of concrete fire protection. When cement hydrates, it chemically combines with a significant amount of water. In the case of fire, as the temperature increases, the hydrated compounds break down and release the water, thus dissipating heat and energy. This means that while the surface of the

concrete may have been subject to high temperatures, the depth of damage may be limited.

After a fire, the appearance of any structure can give the impression of a scene of total destruction. Because of the smoke, everything will be blackened. There will be areas where concrete has cracked and may have spalled. The levels of damage may appear significant but due to concrete's ability to dissipate heat, the actual damage may well be recoverable.

If the temperature of the concrete has not exceeded 300 °C on cooling, the residual strength is commonly considered to not be significantly affected.<sup>49</sup> The reduction in strength is often offset by factors that resulted in the concrete having higher strengths than required by the original structural capacity. A word of caution should be raised as it is often assumed that the concrete strength increases with time beyond that required by the design. For older cements, this was the case, as in order to achieve the required strength at 28 days, the ultimate strength needed to be higher. Cements are more finely ground and cement producing companies have improved quality control systems that mean the factors of safety included to ensure the concrete meets the required 28 days strength are now lower. The ultimate strength achieved may not be significantly greater than that obtained at 28 days.

The temperature at which significant structural deterioration occurs coincides with a color change in many concretes, where the material develops a pink hue. This discoloration is due to the presence of ferrous salts in the aggregates, and may not occur if these are not present. It is important to note that this does not apply in every case, and the levels of heat damage and degradation of the cement should be confirmed using petrographic analysis on samples. Where temperatures exceed 500 °C, the strength is usually severely compromised.

## Glossary

**Glass transition temperature** The temperature at which polymer molecules cease being effectively locked into position and have sufficient rotational energy to be able to coil and uncoil.

**Polymer resin** A polymerized synthetic or chemically modified natural material, including thermoplastic materials such as polyvinyl chloride and thermosetting materials such as epoxy resins, which are used with other components such as fillers to form plastics.

**Thermoplastic** A polymeric material (e.g., nylon) which is capable of being repeatedly softened by increases in temperature and hardened by decreases in temperature.

**Thermoset/thermosetting** A polymeric material (e.g., an epoxy resin) which, upon curing, results in a three-dimensional structure and that decomposes rather than melts upon heating.

**PTFE** Polytetrafluoroethylene

**PVC** Polyvinyl chloride

**PVdC** Polyvinylidene chloride

**PVdF** Polyvinylidene fluoride

**SBR** Styrene butadiene rubber

**SBS** Styrene butadiene styrene triblock copolymer

## Symbols

$\Delta G$  Change in Gibbs's free energy

$\Delta H$  Change in enthalpy

**L** Latent heat of vaporisation

**P** Partial polarity

$\Delta S$  Change in entropy

$T_g$  Glass transition temperature

$T_m$  Melting temperature

## Abbreviations

**ABS** Acrylonitrile butadiene styrene polymers

**DSC** Differential scanning calorimetry

**FEP** Fluorinated ethylene propylene resins

**HIPS** High impact polystyrene

**MBS** Methacrylate butadiene styrene polymers

**PBT** Polybutylene terephthalate

**PEEK** Polyetheretherketone

**PES** Polyether sulfone

**PMMA** Polymethylmethacrylate

**PP** Polypropylene

**PPO** Polyphenylene oxide

**PPS** Polyphenylene sulfide

**PS** Polystyrene

## 3.31.1 Introduction

From ancient times, organic materials, such as beeswax, have been used for surface protection of metallic and other artifacts. The nineteenth and especially the twentieth centuries saw huge advances<sup>1,2</sup> in surface coatings for the protection of metals against corrosion. This development continues apace right up to the present day. Some of the drivers of these developments are not only the ever-present desire to improve protection, but also to find materials and systems which are less polluting and which conform with increasingly stringent environment protection legislation. The latter driver has, for example, led to much work on waterborne coatings<sup>3</sup> to replace systems containing organic solvents, which were traditionally simply lost to the atmosphere. It is also the driving force behind the spectacular rise of polymeric materials which has led to the replacement of metals as the structural material in a vast range of manufactured

items. A glance around any room will reveal many plastic items which formerly would have been metallic.

In the past, corrosion control has involved, in the main, the use of metal alloys, protective coatings, inhibitors, etc. Corrosion problems may now often be circumvented by the use of organic polymers in the form of plastics or rubbers.<sup>1</sup> It must, however, be stressed that such polymeric materials are not totally inert to chemicals in their immediate environment, including, possibly, to metallic substrates or contacts.

### 3.31.2 Definition of 'Plastics'

In this section, both the terms 'polymer' and 'plastic' are encountered. The former is much easier to define than the latter. A polymer, or macromolecule, may be defined as a species with a molar mass much greater than that encountered in common organic substances such as alcohol, petrol, chloroform, etc., and which is comprised of smaller, repetitive molecular units. Although there is no specific definition that can universally define the polymeric (macromolecular) state, a molecular mass of at least several thousand is generally taken as indicating its start. Such polymer molecules may be linear, branched, have a network structure, etc. These different molecular geometries influence the properties of the given polymer very significantly.<sup>4,5</sup>

It is difficult to provide a satisfactory definition of the term 'plastics'. Attempts at reasonably concise definitions tend to include certain materials such as rubbers, adhesives, fibers, glasses and surface coatings which are not usually considered as plastics, and to exclude a number of materials such as bituminous plastics, shellac and polytetrafluorethylene which usually are considered as plastics. In reality, the term becomes defined by common usage rather than by a physical/chemical description. However, in general, it may be said that plastics are usually high-molecular-weight polymers that at some stage in their existence are capable of flow, but may also be brought into a non-fluid form in which they have sufficient toughness and strength to be useful in self-supporting applications. Although they may be self-supporting, this does not exclude the possibility of reinforcing the plastics with fibers, or other fillers, or laminating them with other materials. Sometimes metals are coated with plastics, but usually at a greater thickness than is common with surface coatings such as paint films (which are, of course, also polymers).

The rapid rise of the plastics industry may be attributed to a number of factors. Foremost has been the fact that while many materials of construction

have been subjected to continual increase in their price, the development of the petrochemicals industry and economies of scale have, for most of the time, led to reductions in the prices of plastics materials. Thus, with the passage of time, more and more products constructed from traditional materials have become cheaper to produce from plastics. The trend of increased plastics usage seems bound to continue in the foreseeable future, now driven by our ever-increasing ability to make polymer molecules (plastics) with better controlled molecular architectures<sup>6</sup> and by better processing technologies.<sup>7</sup>

Such a growth also requires, of course, that plastics possess properties suitable for the end uses envisaged. It is now possible, by control of synthesis, by chemical modification, by careful control of the relevant processing technology (injection molding, extrusion, etc.) or by the selective use of additives such as fibers, nanofillers, etc., to make products varying widely in their properties. The following is a list of some of the salient properties expected of plastics materials.

1. Tenacity. While some plastics are rigid and others flexible, all commercial materials show a degree of strength and toughness when stressed rapidly, superior to simple crystals and common glass.
2. Low thermal conductivity.
3. Low electrical conductivity.
4. Low heat resistance compared with common metals. The vast majority of plastics will not withstand 100 °C for extended periods and only a very few highly specialized products will withstand temperatures of 400 °C and above.

### 3.31.3 The Chemical Nature of Plastics

#### 3.31.3.1 Free-Radical Addition Polymerization of Monomers with Double Bonds

In this case, the reactive double bond in a small molecule, such as ethylene or propylene, allows it to join another similar molecule.<sup>5</sup> These small molecules are known as monomer molecules. The chemical equation below shows this process for ethylene. The value of  $n$  in the equation can typically exceed 10 000 and can rise above 1 000 000.

Such a molecule is referred to as a polymer, in this case polyethylene. Styrene, propylene, vinyl

chloride, vinyl acetate, and methyl methacrylate are other examples of monomers that can polymerize in this way. Sometimes, two monomers may be reacted together so that residues of both are to be found in the same chain. Such materials are known as copolymers and are exemplified by ethylene–vinyl acetate copolymers and styrene–acrylonitrile copolymers. If there are three such repeat units in a given polymer, it is termed a terpolymer.

### 3.31.3.2 Step-Growth Polymerization

In this case, reaction between two functional groups occurs, which leads to the production of a polymer and also a small molecule. This is a condensation reaction. A good example of this type of chemistry is the reaction between adipic acid and hexamethylene diamine, which yields nylon-6,6 and water as the small molecule:

Most nylons, polyesters, phenolics and a number of other plastics are produced by this route.<sup>8</sup>

### 3.31.3.3 Rearrangement Polymerization

Here the mechanism resembles step-growth polymerization, but no small molecule is split at each individual reaction step. In the first example, 1,4-butane diol reacts with hexamethylene di-isocyanate to give polyurethane:

In the second,  $\epsilon$ -caprolactam, a ring compound opens up to give nylon-6:

The polymerization of  $\epsilon$ -caprolactam is commonly known as a ring-opening polymerization, a technique also used with other cyclic compounds such as ethylene oxide, propylene oxide and tetrahydrofuran.

### 3.31.3.4 Ionic Polymerization

In the case of ionic polymerization, the growing polymer molecules (commonly referred to as

polymer chains) are temporarily terminated by ionic groups, which may be anionic (anionic polymerization) or cationic (cationic polymerization). The major advantage of this type of polymerization is that it offers good control over the resulting molecular architecture.<sup>8</sup>

Polymers may also be obtained from biological sources.<sup>9,10</sup> Cellulose, the principal constituent of cotton and a major constituent of wood, is such a polymer. So also are lignin, chitin from crustacean shells, natural rubber, gutta percha, and proteins. Sand (silica) may be considered as an inorganic polymer. While many of these are unmodified, some, like cellulose, cannot be considered as plastics in their natural state, but if chemically modified, useful plastics materials such as cellulose acetate, celluloid, and ethyl cellulose may be obtained. Natural rubber is clearly the basis of a huge worldwide industry.

## 3.31.4 The Physical Nature of Plastics

Many polymers, such as polystyrene, consist of long chain-like molecules of high molecular weight. A typical average molecular weight for a polystyrene sample is about 200 000 and since the molecular weight of the monomer is 104 this implies that there are around 2000 repeat units joined together in a typical molecule taken from that sample. It is the case in nearly all plastics that a given sample contains molecules covering a distribution of molecular weights. This distribution, in some cases, may be very wide.<sup>5</sup> Since the backbone carbon–carbon bonds can rotate relatively freely, such molecules are most unlikely to be stretched out, but are more likely to be coiled up into what is referred to as a random-coil conformation.<sup>11</sup>

In the case, for example, of polystyrene, the molecules at room temperature do not have enough rotational energy to twist around the backbone chemical bonds and so, in the mass, the polymer is rigid. On heating above a certain temperature, sufficient energy for such subchain movement is obtained and on application of a shearing stress in processing such as extrusion, the polymer molecules partly uncoil. Chain segments slip past each other and, in the mass, flow occurs. On cessation of stress, slippage ceases, the chains again coil up and, on cooling, the mass again hardens. If desired, the whole process of heating, shearing and cooling may be repeated. Materials that behave in this way are known as

thermoplastics.<sup>7,11</sup> Two points should, however, be noted. Firstly, if cooling is faster than the chain recoiling process, then a frozen-in molecular orientation will result. This can grossly affect the polymer properties, in some cases adversely. Secondly, repeated heating and shearing may be accompanied by changes such as oxidation and polymer degradation, which will limit, in practice, the number of times heating and cooling can be applied on a particular polymer sample. In terms of tonnage, the bulk of plastics produced are thermoplastics, a group that includes the polyethylenes, polypropylene, polystyrene, polyvinyl chloride (PVC), the nylons, polycarbonates and cellulose acetate. There is, however, a second class of materials, the thermosetting plastics.<sup>7,11</sup> They comprise long-chain molecules, similar to a typical thermoplastic molecule, however, as rather smaller molecules. They are formed, often in a mold, into the desired final shape and then subjected to chemical reaction, often by heating, in such a way such that the molecules link with one another to form a cross-linked network as shown in **Figure 1**. As the molecules are now interconnected, they can no longer slide extensively past one another and the material is said to have set, cured or cross-linked. Plastic materials behaving in this way are designated as thermosetting plastics, a term which is also used to include those materials that can be cross-linked with suitable catalysts at room temperature. Important thermosetting plastics include the phenolic resins, melamine-formaldehyde resins, the epoxy resins and unsaturated polyester resins used in glass-reinforced plastics.

**Figure 1** Joining up of (a) long-chain molecules or (b) branched molecules to produce (c) a cross-linked polymer.

### 3.31.4.1 Thermoplastics

Thermoplastics may be considered in four subclasses: (a) amorphous thermoplastics; (b) rubber-modified amorphous thermoplastics; (c) plasticized amorphous thermoplastics, and (d) crystalline thermoplastics.

#### 3.31.4.1.1 Amorphous thermoplastics

These are made from polymers that have a sufficiently irregular molecular structure to prevent them from crystallizing. Examples of such materials include polystyrene and polymethyl methacrylate. The structural irregularity in these examples arises from the free-radical addition polymerization process used in their synthesis. This results in the repeat unit side groups being present in essentially random configurations,<sup>5</sup> which is sufficient to prevent crystallization.

At very low temperatures, these materials are glass-like and rigid. On heating, a temperature is eventually reached where the material softens. If the polymer is of sufficiently high molecular weight, it becomes rubbery above this temperature. The temperature at which this occurs is known as the glass transition temperature ( $T_g$ ),<sup>5,11</sup> and is in effect the temperature at which the polymer molecules have sufficient rotational energy to be able to coil and uncoil. As the individual polymer molecules, in their random-coil conformations, interpenetrate each other, the resulting chain entanglements prevent flow. At higher temperatures there are two possibilities. Polymers of moderate molecular weight may achieve such energy that they can flow, while high molecular weight materials may decompose before the flow point is reached. This is shown schematically in **Figure 2**,

**Figure 2** Temperature-molecular weight phase diagram for amorphous polymers.

which indicates the phases in which this type of polymer can occur. It should be stressed that the boundary lines will change position with change of polymer type.

It can be seen that up to a certain molecular weight a polymer may be processed either as a liquid (by injection molding, extrusion, etc.) or as a rubber (by vacuum forming, sheet blowing, hot pressing). In the case of a polymer of much higher molecular weight, it can be seen that it can only be shaped in the rubbery state, and if it is intended to be processed by, say, injection molding, then the molecular weight may first have to be reduced. An important illustration of this is with well-known acrylic materials such as Perspex (polymethyl methacrylate), which can have too high a molecular weight to be injection-molded.

It is possible to make some generalizations about the properties of amorphous thermoplastics.

1. The  $T_g$  will determine the maximum temperature of use of the material as a rigid thermoplastic. For amorphous rubbers, the  $T_g$  value will determine the minimum temperature of use.
2. Below  $T_g$ , most amorphous polymers show a more or less linear stress-strain curve with no yield point. The tensile strengths are typically around 50 MPa, elongation at failure usually less than 10%, and the elastic modulus typically around 2.5 GPa. Since the area under the curve provides a measure of the energy required to rupture the specimen, and since this area is small, such polymers will have a low impact strength (which is closely related to the energy to break) and will break with a brittle fracture.
3. They are generally more permeable to gases than crystalline polymers. This is more so above  $T_g$  than below.
4. They usually have a much wider range of solvents than crystalline polymers.

#### **3.31.4.1.2 Rubber-modified amorphous polymers**

The brittleness of amorphous polymers has been a hindrance in their commercial development. However, for reasons now substantially understood, the addition of rubbery polymers as dispersed droplets into the glassy polymer can often lead to substantial increases in impact strength,<sup>12</sup> albeit usually at some cost to tensile strength and, in many cases, to transparency.

The most important polymers of this important class are as follows.

1. High-impact polystyrene (a polystyrene modified with a styrene-butadiene rubber (SBR) or a polybutadiene rubber).
2. ABS, which is based on a copolymer of acrylonitrile, butadiene and styrene.
3. Methacrylate-butadiene-styrene polymers (MBS) and related materials, which are chemically similar to ABS but are often available in transparent form.
4. Rubber toughened epoxy resins.
5. High-impact PVC; in this case the impact modifiers are not always rubbers, but the mechanism of their action is probably similar.

#### **3.31.4.1.3 Plasticized amorphous thermoplastics**

Certain plastics may be mixed with high boiling temperature, low-volatility liquids to give products of lower  $T_g$ . The most important example of this class occurs with PVC, which is often mixed with liquids such as di-*iso*-octyl phthalate, tritolyl phosphate, or other diesters to bring the  $T_g$  below room temperature. These liquids work by increasing the free volume in the materials, thereby facilitating the segmental motions that constitute the glass transition process. If their volatility is a problem in a given case, it may be possible to use either a polymeric plasticizer<sup>13</sup> or a chemically bound plasticizer.<sup>14</sup> The resultant plasticized PVC is flexible and to some degree quite rubbery. Other commonly plasticized materials are cellulose acetate and cellulose nitrate.

It is essential to appreciate that such plasticizers may also considerably modify the chemical properties of the plastic material since the plasticizer may be readily extracted by certain chemicals and chemically attacked by others while the base polymer may be unaffected.

#### **3.31.4.1.4 Crystalline thermoplastics**

While polymers such as polyethylene and nylon-6,6 do not show any regular external form, which is characteristic of crystals, closer examination reveals that they have many properties common to crystalline materials. They exhibit distinct X-ray diffraction patterns<sup>5</sup> and exhibit specific melting in differential scanning calorimetry (DSC).<sup>5</sup> Although the exact nature of this crystallinity is not fully resolved in some cases, it would appear that polymer segments pass through zones in which molecular arrangement is highly ordered, that is, crystalline. In some ways these zones act like knots, or cross-links, holding the individual molecules of such materials together.

The effect of heating crystalline polymers from low temperatures is more complex than with amorphous polymers. Initially, the material is rigid and hard. As the temperature goes through the  $T_g$ , light crystalline materials soften slightly and become leather-like, but highly crystalline materials show relatively little change in properties. Further heating results in the crystals melting, often over quite a wide temperature range, and the polymer becomes rubbery. Whether or not it melts or decomposes first on further increase in temperature will depend on both the particular polymer and its molecular weight.

A typical phase diagram for such polymers is given in **Figure 3**. With such crystalline polymers, the melting point,  $T_m$ , replaces the  $T_g$  as the factor usually determining the maximum service temperature of thermoplastics and minimum service temperature of rubbers. However, it is more difficult to make generalizations about properties. The following remarks may, however, be pertinent for crystalline polymers.

1. Below  $T_g$ , tensile strengths are usually at least as high for crystalline polymers as for amorphous ones. Between  $T_m$  and  $T_g$ , the strength and rigidity will be very dependent on the degree of crystallinity and to some extent on the molecular weight. Tensile strengths commonly range from below 10 to around 90 MPa.
2. In most cases, crystal densities differ from those of amorphous polymers. This leads to differences in refractive index, which in turn cause scattering of light at boundaries between amorphous and crystalline zones. Such materials are opaque, except in certain instances where the crystal structure can be carefully oriented to prevent such scattering of light.

**Figure 3** Temperature-molecular weight phase diagram for crystalline polymers.

3. The close molecular packing makes diffusion more difficult than with amorphous polymers compared under similar circumstances, that is, either below  $T_g$ , or above  $T_g$  but below  $T_m$ , of the crystalline polymer.
4. Thermodynamic considerations lead to considerable restriction in the range of solvents available for such polymers.<sup>5,11</sup>

### 3.31.4.2 Thermosetting Plastics

If glycerol, a trihydric alcohol, reacts with phthalic anhydride, three ester links can be made from each glycerol unit. Continued reaction will eventually cause the molecules to link up in a three-dimensional network in which, theoretically at least, the whole polymer mass becomes one giant molecule.

For reasons of production feasibility, such cross-linked plastics are normally prepared in two stages. In the first stage, either a low-molecular-weight branched polymer or a higher-molecular-weight linear (unbranched) polymer is produced. Such materials are thermoplastic and in most cases soluble in some solvents. At a convenient (later) time, this intermediate is subjected to heat, electromagnetic radiation (such as ultraviolet), or chemical reactants, such that the branched molecules join together, or the linear polymers cross-link, thereby producing an infusible, insoluble material. Since, in the early days of the plastics industry, the cross-linking processes required heat, these materials became known as 'thermosetting plastics.' Today this term is commonly extended to materials which can cross-link at room temperature: for example, many organic coating systems (or paints).

Because thermosetting plastics have an irregular form, they are amorphous, and because of their network structure, they are invariably rigid. They do not dissolve without decomposition, but may swell in appropriate solvents, the amount of swelling decreasing with increasing cross-link density. Well-known thermosetting plastics include the phenolics, urea-formaldehyde and melamine-formaldehyde resins, unsaturated polyesters and epoxy resins.

### 3.31.4.3 Reinforced Plastics

The mechanical properties of plastic materials may often be considerably enhanced by embedding fibrous materials in the polymer matrix.<sup>15</sup> While such techniques have been applied to thermoplastics, the greatest developments have taken place with the thermosetting plastics. The most common reinforcing materials are

glass and cotton fibres,<sup>16</sup> but many other materials including paper, carbon fiber, inorganic whiskers, particulates including nanoscale particulates,<sup>15</sup> are used. Reinforcing fibers normally have a modulus of elasticity that is substantially greater than the resin, so that under tensile stress much of the load is borne by the fibers. The modulus of the composite is, therefore, intermediate to that of the fiber and of the resin.

In addition to the nature of resin and fiber, the laminate properties also depend on the degree of bonding between the two main components and on the presence of other additives, including entrained air bubbles. Because of this, some parts, fabricated by simple hand build-up techniques, may exhibit strengths no better, or even worse, than unreinforced materials. This problem is often worst with glass fibers, which are, therefore, normally treated with special finishes to improve the resin–glass bond.

The highest mechanical strengths are usually obtained when the fiber is used in fine fabric form, but for many purposes the fibers may be used in mat form, particularly glass fiber. The chemical properties of such laminates are largely determined by the nature of the polymer, but capillary attraction along the fiber–resin interface can occur when some of these interfaces are exposed at a laminate surface. In such circumstances, the resistance of both the reinforcement and the matrix must be considered when assessing the suitability of a laminate for use in chemically demanding situations. For more information, the reader is referred to the article on polymer–matrix composites.

### 3.31.5 Polymer Orientation

It is not difficult to appreciate that if polymer molecules are aligned, as in **Figure 4(a)**, then a much higher tensile strength will be obtained if a test is carried out in the X–X direction as opposed to the Y–Y direction. It is also not difficult to understand

**Figure 4** Polymer segment alignment: (a) parallel and (b) random.

why such a material has lower impact strength than a randomly coiled mass of molecules, **Figure 4(b)**, because of the ease of cleavage of the material parallel to the X–X direction.<sup>15</sup>

Similar remarks may also be made where crystal structures, or fiber reinforcements, are aligned rather than the individual molecules. For fibers and filaments such orientation is desirable, but for solid objects where impact strength is often more important than tensile strength such orientation is usually unwelcome. It can also have further unwanted effects. This arises from the fact that oriented molecules are thermodynamically unstable and will at the first opportunity try to achieve random-coil conformations. Thus, on heating samples up to temperatures near  $T_g$ , severe distortion can occur, leading to warped moldings.

Another serious effect, solvent stress cracking,<sup>17</sup> occurs with liquids which are not in themselves solvents but which may wet the polymer surfaces. These facilitate relief of frozen-in stresses by surface cracking, which can be a severe problem in using many injections and blow moldings with specific chemicals. Examples of this are white spirit with polystyrene, carbon tetrachloride with polycarbonates and soaps and silicone oils with low-molecular-weight polyethylenes.

In addition to orientation in one direction (monoaxial orientation), biaxial orientation is possible. This is achieved when the sheet is stretched in two directions, resulting in layering of the molecules. This can increase the impact strength, tensile strength and solvent cracking resistance of polymers, and with crystalline plastics the polymer clarity may also be improved.

### 3.31.6 The Chemical Properties of Polymers

It is common practice to talk about the chemical resistance of polymers, unaware of the fact that this can mean different things. To avoid this it is probably wiser to differentiate between the following.

1. Resistance of a polymer to chemical attack resulting in breakdown of some covalent bonds and the formation of new ones. This could involve molecular breakdown initiated by heat or radiation, including ultraviolet light.
2. Resistance to dissolution by liquids.
3. Resistance to cracking in aggressive environments.
4. Permeability to gases and liquids.

It is also important to bear in mind that, for specific end uses, polymers are commonly mixed with a number of additives such as plasticizers, stabilizers, antioxidants, fillers, fire retardants, pigments, dyes and other polymers, and that this may well have an important influence on their chemical properties. The following discussion will, however, be confined to pure polymers.

### 3.31.6.1 Resistance to Chemical Attack

Expressed simply, the resistance of a polymer to chemical attack may be said to be determined by the following factors:

- the nature of the chemical bonds present,
- interactions between chemical groups that occur repeatedly along the molecular chain, and
- the presence of occasional 'weak-links.'

In commercial polymers, there are a rather limited number of chemical bond types to be found and it is possible to make a number of general observations about the chemical reactivity in the following list of examples.<sup>5,8,18</sup>

1. Polyolefins such as polyethylene and polypropylene contain only C–C and C–H bonds and may be considered simply as high-molecular-weight paraffins. Like the simpler paraffins, they are somewhat inert, and their major chemical reaction is a substitution reaction, for example, halogenation. In addition, the branched polyethylenes and all the higher polyolefins contain tertiary carbon atoms which are reactive sites for oxidation. Because of this, it is necessary to add antioxidants to stabilize the polymers against such oxidation. Some polyolefins may be cross-linked by peroxides.
2. Polytetrafluoroethylene (Teflon) contains only C–C and C–F bonds. These are both very stable and the polymer is exceptionally inert.<sup>19</sup> A number of other fluorine-containing polymers are available, which may contain in addition C–H and C–Cl bonds. These are somewhat more reactive, and those containing C–H bonds may be cross-linked by peroxides and certain diamines and diisocyanates.
3. Many polymers, such as the diene rubbers, contain double bonds. These will react with many agents such as oxygen, ozone, hydrogen halides and halogens. Ozone, and in some instances oxygen, will lead to scission of the main chain at the site of the repeat-unit double bond and this will have a

catastrophic effect on the molecular weight. The rupture of one such bond per chain will halve the average molecular weight.

4. Ester, amide, and carbonate groups are susceptible to hydrolysis. When such groups are found in the main chain, their hydrolysis will also result in a reduction of molecular weight. Where hydrolysis occurs in a side chain, the effect on molecular weight is usually insignificant. The presence of benzene rings adjacent to these groups may offer some protection against hydrolysis, except where organophilic hydrolyzing agents are employed.
5. Hydroxyl groups are extremely reactive. These occur attached to the backbones, for example, of cellulose and polyvinyl alcohol.
6. Benzene rings in both the backbone structure and on the side groups can be subjected to substitution reactions. Such reactions do not normally cause great changes in the fundamental nature of the polymer. They seldom lead to chain scission or cross-linking. However, the phenolic resins provide an important exception to this.

There are numerous examples of chemical reactions consequent upon chemical groups that occur repeatedly along a chain. In some cases, the reaction occurs randomly between adjacent pairs of groups such as in the reaction between aldehydes and polyvinyl alcohol and of zinc dust with polyvinyl chloride:

In other instances the reactions appear to occur in sequence down individual chains, for example, in the depolymerization reactions of polyformaldehyde (polyacetal) and polymethyl methacrylate, which are referred to sometimes as unzipping reactions.

In other cases, cyclization reactions can occur such as on heating polyacrylonitrile.

It is commonly found that polymers are less stable, particularly to molecular breakdown at elevated temperatures, than low-molecular-weight compounds containing similar groupings. In part, this may be due to the regular repetition of groups along a chain as discussed above, but more frequently it is due to the presence of weak links along the chain. These may be at the end of the chain (terminal) arising from specific mechanisms of chain initiation and/or termination, or nonterminal, and due to such factors as impurities that become built into the chain, an aberration in the *modus operandi* of the polymerization process or, perhaps, to branch points.<sup>20</sup>

The combination of weak links and unzipping can be catastrophic and has been a particular problem in the commercial development of some polymers, in particular polyacetals.<sup>21</sup>

### 3.31.6.2 Polymer Solubility

The solution properties of polymers have been subjected to intensive study, in particular to complex mathematical treatment.<sup>5,22,23</sup> This section will, however, confine the discussion to a qualitative and practical level.<sup>5</sup>

One chemical will be a solvent for another if the molecules are able to co-exist on a molecular scale, that is, the molecules show no tendency to separate. In these circumstances, the two species are said to be compatible. The definition concerns equilibrium properties and gives no indication of the rate of solution, which will depend on other factors such as temperature, the molecular size of the solvent and the size of voids in the solute.

Molecules of two different species will be able to coexist if the force of attraction between different molecules is not less than the forces of attraction between two like molecules of either species. This is shown more clearly by reference to Figure 5, which shows two types of molecules A and B. The average forces between the like molecules are  $F_{AA}$  and  $F_{BB}$ ,

and the average forces between dissimilar molecules are  $F_{AB}$ . If  $F_{AA}$  was the largest of these three forces, then the A molecules would tend to congregate or cohere, rejecting the B molecules. A similar phase separation would occur if  $F_{BB}$  was the greatest.

It is, therefore, seen that only when  $F_{AB} \geq F_{AA}$  and  $F_{AB} \geq F_{BB}$  will coexistence or compatibility be possible. Obviously, if it is possible to obtain some measure of these forces, it should be possible to make predictions about polymer solubility. What then is a suitable measure of the forces holding like molecules together? One would expect the latent heat of vaporization,  $L$ , to exceed that cohesion energy by an amount corresponding to the work done by evaporation, an amount approximating to  $RT$ , where  $R$  is the gas constant and  $T$  the absolute temperature. Such a diagram of  $(L - RT)$  might be a sufficient measure if all of the molecules were of about the same size.

However, it is reasonable to suppose that compatibility should not be greatly affected by molecular size and that the shorter polymer molecules in Figure 6(a) should be just as compatible as the longer ones in Figure 6(b), although their theoretical latent heats of vaporization will be greatly different. In such circumstances, a reduced diagram of  $(L - RT)/M$  will give a measure of intermolecular energy per unit weight. Similarly, a measure of the intermolecular

**Figure 5** Two different molecular species will be compatible if  $F_{AB} \geq F_{AA}$  and  $F_{AB} \geq F_{BB}$ . In other circumstances the molecules will tend to separate if they have sufficient energy for molecular movement.

**Figure 6** Polymer molecules: (a) short and (b) long.

or cohesion energy per unit volume will be given by the following expression, where  $D$  is the density.

$$\frac{L - RT}{M/D}$$

This expression is known as the cohesive energy density<sup>5,24</sup> with units of megapascal. The square root of this expression is more commonly encountered in quantitative studies and is known as the solubility parameter and given the symbol  $\delta$ .

$$\delta = \sqrt{\frac{L - RT}{M/D}} \text{MPa}^{1/2}$$

The solubility parameter is, thus, an experimentally determinable property, at least for low-molecular-weight materials. In the case of polymers that cannot be vaporized without decomposition, a method of calculating from a knowledge of structural formula has been devised by Small and others.<sup>24,25</sup> It is now possible to provide an estimate of  $F_{AA}$  and  $F_{BB}$ , but the magnitude of  $F_{AB}$  has to be considered separately for each different system.

### 3.31.6.2.1 Amorphous nonpolar polymers and amorphous nonpolar solvents

It is generally assumed in these circumstances, by analogy with gravitational and electrostatic attractions, that  $F_{AB}$  will be equal to the geometric mean of  $F_{AA}$  and  $F_{BB}$ . Thus, if by definition  $F_{AA} > F_{BB}$ , then,  $F_{AA} > F_{AB} > F_{BB}$ . Considering these conditions, it can be seen that compatibility will occur between amorphous nonpolar polymers and solvents only when  $F_{AA} = F_{AB} = F_{BB}$ ; that is, when polymer and solvent

have similar solubility parameters (in practice to within about  $2 \text{MPa}^{1/2}$ ). Reference to the values of  $\delta$  in **Tables 1 and 2** provides examples of this. For example, natural rubber (unvulcanized) ( $\delta = 16.5$ ) is soluble in toluene ( $\delta = 18.2$ ) and carbon tetrachloride ( $\delta = 17.5$ ) but not in ethanol ( $\delta = 25.9$ ). Cellulose diacetate ( $\delta = 23.2$ ) is soluble in acetone ( $\delta = 20.4$ ), but not in methanol ( $\delta = 29.6$ ) or toluene ( $\delta = 18.2$ ). It should be noted that apart from the problem of achieving a molecular level of dispersion, it is not necessary for the solvent to be liquid; it may be an amorphous solid. Such tables are of greatest use with nonpolar materials with values of  $\delta$  not exceeding  $19.4 \text{MPa}^{1/2}$  and when the polymers are amorphous.

### 3.31.6.2.2 Crystalline nonpolar polymers and amorphous solvents

Most polymers of regular structure will crystallize if cooled below the melting point,  $T_m$ . This is in accordance with the thermodynamic law that a process will occur only if there is a decrease in Gibbs free energy ( $-\Delta G$ ) in going from one state to another. Such a decrease occurs on crystallization as the molecules pack in a regular fashion. Since a process occurs only when it is accompanied by a decrease in free energy, there is no reason why a crystalline nonpolar polymer should dissolve in a solvent at temperatures well below the melting point. However, as the melting point is approached, the  $T \Delta S$  term in the equation below increases.

$$\Delta G = \Delta H - T \Delta S$$

**Table 1** Solubility parameters ( $\delta$ ) of polymers

Polymer	$\delta \text{ (MPa}^{1/2}\text{)}$	Polymer	$\delta \text{ (MPa}^{1/2}\text{)}$
Polytetrafluorethylene	12.6	Polyethyl acrylate	18.8
Polychlorotrifluoroethylene	14.7	Polysulfide rubber	18.4–19.2
Polydimethyl siloxane	14.9	Polystyrene	18.8
Ethylene-propylene rubber	16.1	Polychloroprene rubber	18.8–19.2
Polyisobutylene	16.1	Polymethyl methacrylate	18.8
Polyethylene	16.3	Polyvinyl acetate	19.2
Polypropylene	16.3	Polyvinyl chloride	19.4
Polyisoprene (natural rubber)	16.5	Bisphenol A polycarbonate	19.4
Polybutadiene	17.1	Polyvinylidene chloride	20.0–24.9
Styrene-butadiene rubber	17.1	Ethylcellulose	17.3–21.0
Poly- <i>t</i> -butyl methacrylate	16.9	Cellulose dinitrate	21.5
Poly- <i>n</i> -butyl methacrylate	17.7	Polyethylene terephthalate	21.8
Poly- <i>n</i> -hexyl methacrylate	17.5	Acetal resins	22.6
Polybutyl acrylate	18.0	Cellulose diacetate	23.1
Polyethyl methacrylate	18.4	Nylon 66	27.7
Polymethylphenyl siloxane	18.4	Polymethyl $\alpha$ -cyanoacrylate	28.8
		Polyacrylonitrile	28.8

**Table 2** Solubility parameters ( $\delta$ ) and partial polarities ( $P$ ) of some common solvents

<i>Solvent</i>	$\delta$ (MPa <sup>1/2</sup> )	<i>P</i>	<i>Solvent</i>	$\delta$ (MPa <sup>1/2</sup> )	<i>P</i>
Dimethylpropane	12.9	0	Chloromethane	19.8	–
2-Methylpropene	13.7	0	Dichloromethane	19.8	–
Hexane	14.9	0	1,2-Dichloroethane	20.0	0
Ethoxyethane	15.1	0.03	Cyclohexane	20.2	–
Octane	15.5	0	Carbon disulfide	20.4	0
Methylcyclohexane	15.9	0	Acetone	20.4	0.69
2-Methylpropanoate	16.1	–	Octanol	21.0	0.04
2,4-Dimethylpentan-3-one	16.3	0.3	Butanenitrile	21.4	0.72
2-Methyl butyl acetate	16.3	–	Hexanol	21.8	0.06
Cyclohexane	16.7	0	2-Butanol	22.0	0.11
2,2-Dichloropropane	16.7	–	Pyridine	22.2	0.17
3-Methyl-1-butyl acetate	16.9	–	Nitroethane	22.6	0.71
Pentylacetate	17.3	0.07	Butanol	23.3	0.10
Tetrachloromethane	17.5	0	Cyclohexanol	23.3	0.08
Hexan-2-one	17.7	0.4	2-propanol	23.4	–
Piperidine	17.7	–	Propanol	24.3	0.15
Xylene	18.0	0	Dimethyl formamide	24.7	0.77
Methoxymethane	18.0	–	Hydrogen cyanide	24.7	–
Toluene	18.2	0	Acetic acid	25.7	0.30
1,2-Dichloropropane	18.4	–	Ethanol	25.9	0.27
Ethyl acetate	18.6	0.17	Formic acid	27.5	–
Benzene	18.8	0	Methanol	29.6	0.39
4,4-Hydroxymethylpentan-2-one	18.8	–	Phenol	29.6	0.06
Trichloromethane	19.0	0.02	Glycerol	33.7	0.47
1,1,2-Trichloroethene	19.0	0	Water	47.7	0.82
Tetrachlorethane	19.2	0.01			
2-Hydroxyethoxyethan-2-ol	19.6	–			

Here,  $T$  is the absolute temperature,  $\Delta S$  the entropy change, and  $\Delta H$  the enthalpy change. So, with increasing temperature,  $\Delta G$  can become negative and dissolution can therefore occur.

Hence, at room temperature, there are no solvents for polyethylene, polypropylene, poly-4-methylpentene-1, polyacetal or polytetrafluoroethylene, but at temperatures of about 30°C below their melting points solvents of similar solubility parameter are effective. It should also be noted that at room temperature swelling may occur in the amorphous zones of the polymer in the presence of solvents of similar solubility parameter.

### 3.31.6.2.3 Amorphous nonpolar polymers and crystalline solvents

This situation is identical to the previous one, and occurs, for example, when paraffin wax is mixed into rubber above its melting point. On cooling, the paraffin wax tends to crystallize, some of it on the surface of the rubber. Such a bloom is one way of protecting a diene rubber from ozone attack.

### 3.31.6.2.4 Amorphous polar polymers and solvents

Molecules are held together by one, or more, of four types of forces: dispersion, dipole, induction and hydrogen bonding. In the case of aliphatic hydrocarbons, the so-called dispersion forces predominate. However, many covalent bonds contain dipoles, with one end being partially positively charged and the other partially negatively charged. Such dipoles may interact with dipoles on other molecules and lead to enhancement of the total intermolecular attraction. Molecules that possess dipoles and interact in this way are said to be polar. Many well-known solvents (e.g., water) and polymers (e.g., PVC) are polar, and it is generally considered that for interaction both the solubility parameter and their degrees of polarity should match. This is usually expressed in terms of partial polarity,<sup>24</sup> which expresses the fraction of total forces due to dipole bonds. Some figures for partial polarities ( $P$ ) for solvents are given in Table 2, but there is a lack of quantitative data on the partial polarities of polymers. A comparison of

polarities has to be made by common sense rather than a quantitative approach. For example, hydrocarbon polymers would be expected to have a negligible polarity and would then be more likely to dissolve in toluene rather than diethyl ketone, although both have similar solubility parameters.

### 3.31.6.2.5 Crystalline polar polymers and solvents

It has already been pointed out that at temperatures well below their melting point crystalline nonpolar polymers will not interact with solvents, and similar considerations can apply to a large number of polar crystalline polymers. It has, however, been possible to find solvents for some polar, crystalline polymers such as the nylons, polyvinyl chloride and the polycarbonates. This is because of specific interactions between polymer and solvent that may often occur by, for example, hydrogen bonding.

For example, nylon-6,6 will dissolve in formic acid, glacial acetic acid and phenol, solvents that not only have similar solubility parameters but also are capable of acting as proton donors while the carbonyl groups on the nylon act as proton acceptors.

More interesting examples are given with PVC and the polycarbonate of bis-phenol A – both are slightly crystalline polymers. It is noticed here that while dichloromethane is a good solvent and tetrahydrofuran a poor solvent for the polycarbonate, the reverse is true for PVC, yet all four materials have similar solubility parameters. It would seem that the explanation is that a form of hydrogen bonding occurs between the polycarbonate and methylene chloride and between PVC and tetrahydrofuran. In other words, there is a specific interaction between each solvent pair:

Many studies have been made to assess the propensity to hydrogen bonding of chemical structures.<sup>24</sup> As a result, the following broad generalizations may be made.

1. Proton donors include highly halogenated compounds such as chloroform and pentachlorethane; less halogenated materials are weaker donors.
2. Polar acceptors include, in roughly descending order of strength, amines, ethers, ketones,

aldehydes, and esters, with aromatic materials usually being more powerful than aliphatic ones.

3. Some materials such as water, alcohols, carboxylic acids, and primary and secondary amines may be able to act simultaneously as proton donors and acceptors. Cellulose and polyvinyl alcohol are two polymers that also function in this way.
4. A number of solvents such as the hydrocarbons, carbon disulfide and carbon tetrachloride are quite incapable of forming hydrogen bonds.

### 3.31.6.2.6 Rubbers and thermosetting plastics

Covalently cross-linked rubbers and plastics cannot dissolve without chemical change. They will, however, swell in solvents of similar solubility parameter, the degree of swelling decreasing with increasing cross-link density. The solution properties of the thermoplastic elastomers, which are two-phase materials, are much more complex and dependent on whether or not the rubber phase and the thermoplastic domains are dissolved by the solvent.

### 3.31.6.3 Resistance to Cracking in Aggressive Environments

It has been found with many rigid plastics materials that, under stresses well below the normal yield stress, cracking occurs in environments where the polymer will be unaffected when free of stress. The mechanism for this stress-cracking phenomenon is not fully understood and, indeed, there may well be different mechanisms in different circumstances. There do, however, appear to be four main types.

- Solvent cracking of amorphous polymers.
- Solvent cracking of crystalline polymers.
- Environmental stress cracking.
- Thermal cracking.

Examples of solvent cracking of amorphous polymers<sup>26</sup> are polystyrene with white spirit, polycarbonate with methanol and polysulfone with ethyl acetate. The propensity to solvent stress cracking is, however, far from predictable, and intending users of a polymer should check on this before use.

In the case of crystalline polymers, it may be that solvents can cause cracking by activity in the amorphous regions of these more complex morphologies. Examples of this are benzene and toluene with polyethylene. In polyethylene, however, a greater problem is that of environmental stress cracking,<sup>17</sup> which

occurs with materials such as soap, alcohols, surfactants and silicone oils. Many of these are highly polar materials that cause no swelling, but are simply absorbed either into, or on to, the polymer. This appears to weaken the surface and allows cracks to propagate from minute flaws. Cracking caused by heat (thermal cracking) appears to act in a similar manner, but in this case oxygen is the aggressive environment, becoming active at 70–80 °C with some polyethylenes.

### 3.31.6.4 Diffusion

The efficacy of polymers when used to protect metals from corrosive environments is, of course, strongly influenced by their efficiency as barrier materials. When applied to metals by some techniques, such as fluidized-bed coating, there is always the danger of ‘macrodiffusion’ through pinholes, which are gross imperfections in the surface region and which do not have to be visible to be very much greater than the dimensions of penetrating molecules.

Assuming, however, that the film is continuous, the concern then is with the permeability of the corrosive fluids in the polymer film. This involves both the dissolution of the fluid into the polymer, which will be determined by the conditions discussed previously, and the rate of diffusion of the fluid through the polymer. This has been discussed elsewhere<sup>18,27</sup> in detail, but may be summarized as follows.

1. The lowest diffusion rates occur with crystalline polymers below the  $T_g$ , since there is very little space through which diffusing molecules may pass.
2. Amorphous polymers below the  $T_g$  have a somewhat higher permeability, but diffusion is still difficult.
3. For amorphous polymers above the  $T_g$ , that is, in the flexible and rubbery states, there is more space (free volume) available through which diffusing molecules may pass, and so these materials show comparatively high diffusion rates with low-molecular-weight diffusing fluids.
4. For crystalline polymers between  $T_g$  and  $T_m$ , the diffusion rate is very dependent on the degree of crystallization.

## 3.31.7 Review of Commercial Plastics

### 3.31.7.1 Amorphous Thermoplastics

#### 3.31.7.1.1 Polyvinyl chloride

PVC<sup>28</sup> is one of the two most important plastics in terms of tonnage and shows many properties typical

of rigid amorphous thermoplastics. However, PVC is not a truly amorphous polymer in that it has short stereoregular repeat unit sequences which can lead to crystallinity values up to about 10 vol.%. PVC softens at about 70 °C, burns only with difficulty, but is thermally unstable. To reduce this instability, stabilizers are invariably compounded into the polymer.

Being slightly crystalline, there are a few good solvents, the best known of which are nitrobenzene, cyclohexanone, and tetrahydrofuran. When mixed with certain nonvolatile solvents such as some phthalates, adipates, and phosphates, flexible materials are obtained, which are referred to as plasticized PVC.

In order to improve toughness, many rubbers and other soft polymers may be used as additives to modify the compound. Some copolymers based on vinyl chloride are available of which the most important are the vinyl chloride–vinyl acetate materials used in flooring compositions and surface coatings.

#### 3.31.7.1.2 Polystyrene

The volume of expanded polystyrene (PS) produced probably exceeds the total volume production of all other plastics (excluding the polyurethanes). About half the tonnage of polystyrene produced is in the form of high-impact polystyrene (HIPS): a complex blend containing styrene–butadiene rubber or polybutadiene.<sup>7,19</sup> Styrene–acrylonitrile (SAN) has improved heat resistance, oil resistance and slightly better impact strength.

#### 3.31.7.1.3 Acrylonitrile–styrene–butadiene polymers (ABS)

These are complex blends and copolymers of excellent toughness.<sup>7,19</sup>

#### 3.31.7.1.4 Poly(methyl methacrylate)

Poly(methyl methacrylate) (PMMA)<sup>7,19</sup> is used mainly where high light transmission and excellent weathering properties are of greatest importance. This polymer is the most well known of a very wide range of acrylic polymers that find use as rubbers, fibers, plastics, adhesives and surface coatings. The sheet forms (Perspex, Plexiglas, Oroglass) are often of high molecular weight and dissolve only with some difficulty.

#### 3.31.7.1.5 Polyvinyl acetate and derivatives

Polyvinyl acetate is used largely for coating applications,<sup>7,19</sup> but the derivative polyvinyl alcohol will, provided there are some residual acetate groups, dissolve in water. Reaction products of polyvinyl

alcohol with aldehydes such as polyvinyl formal and polyvinyl butyral are also commercially available materials.

#### **3.31.7.1.6 Cellulose-based plastics**

These long-established materials<sup>9,10</sup> have limited chemical resistance. Ethyl cellulose is, however, often used in conjunction with mineral oil for hot-melt strippable coatings for protecting metal parts against corrosion and marring during transport and storage.

### **3.31.7.2 Crystalline Plastics**

#### **3.31.7.2.1 Polyethylene**

The polyethylenes (high density, low density, linear low density, etc.) are among the largest tonnage polymeric materials produced worldwide.<sup>7,19</sup> They are attacked by only a few chemicals, are not swollen by water or common organic solvents, but are susceptible to environmental stress cracking in the presence of certain detergents, esters, alcohols and silicones. Commercial materials vary in the regularity of their molecular structure, the more regular grades having a higher density and rigidity and lower gas permeability.

#### **3.31.7.2.2 Polypropylene**

Polypropylene has similar chemical properties to polyethylene, but is less susceptible to environmental stress cracking. It may also be used at somewhat higher temperatures.<sup>7,19</sup>

#### **3.31.7.2.3 Other polyolefins**

A variety of other crystalline polyolefins such as polybutene-1 (improved creep resistance over polyethylene), poly-4-methyl pentene-1 (excellent temperature deformation resistance) and ethylene-vinyl acetate polymers (greater flexibility) are available.<sup>7</sup>

#### **3.31.7.2.4 Polytetrafluorethylene**

Polytetrafluorethylene (PTFE) does not absorb water, has no solvents and is almost completely inert to chemical attack, except by molten alkali metals and sodium in liquid ammonia. Furthermore, it does not soften below 320°C, is electrically inert and has a very low coefficient of friction. It is more expensive than general-purpose plastics, requires special fabrication techniques, is degraded by high-energy radiation and has a low creep resistance.<sup>7,19</sup>

#### **3.31.7.2.5 Other fluorine-containing plastics**

These materials<sup>7,19</sup> in general, attempt to compromise between the exceptional end-use properties of PTFE and the greater ease of processing of other thermoplastics. Examples include polychlorotrifluoroethylene, tetrafluoroethylene-hexafluoropropylene copolymers (FEP resins), and polyvinylidene fluoride. Polyvinyl fluoride is available in film form with excellent weathering resistance.

#### **3.31.7.2.6 Polyamides (nylons)**

The main types of nylon<sup>7,19</sup> are oil and petrol resistant, but on the other hand susceptible to high water absorption and hydrolysis. There are a few solvents which include phenol and formic acid. Special grades include a water-soluble nylon, amorphous copolymers and low-molecular-weight grades used in conjunction with epoxy resins. Transparent amorphous polyamides are also now available.<sup>7</sup>

#### **3.31.7.2.7 Polyformaldehydes (polyoxymethylenes, polyacetals)**

These are physically similar to general-purpose nylons, but with greater stiffness and lower water absorption. There are no common solvents, but swelling occurs in liquids of similar solubility parameter. Poor resistance to ultraviolet light and limited thermal stability are two disadvantages of these materials.<sup>7,19</sup>

#### **3.31.7.2.8 Other polyethers**

The chlorine-containing polyether 'Penton' has excellent resistance to mineral acids, strong alkalis and most common solvents.<sup>29</sup> However, it is not recommended for use with oxidizing acids such as fuming nitric acid. Poly-2,6-dimethyl phenylene oxide (PPO) and certain related materials are similar to the nylons, but have superior heat resistance. These polymers are somewhat liable to stress-cracking problems.<sup>7,19</sup> Several polyethers are used as intermediates in the preparation of polyurethane foams, while others such as polyethylene glycol are water soluble.<sup>7</sup>

#### **3.31.7.2.9 Linear polyesters**

Polyesters<sup>7,19</sup> may be obtained in a wide variety of forms including rubbers, fibers, films, laminating resins, surface coatings and thermoplastic molding powders. The last named are somewhat similar to the nylons, but are more rigid. Chemical applications are limited because of their sensitivity to alkaline solutions and hot water.

**3.31.7.2.10 Polycarbonates and polysulfones**

These are tough materials with heat resistance better than most thermoplastics. They are resistant to attack by acids and alcohols, but the polycarbonates are sensitive to alkalis.<sup>7,19</sup>

**3.31.7.3 Thermosetting Resins**

These materials<sup>7,19</sup> often have better heat resistance than thermoplastics. Thermosetting resins are used in a variety of guises including surface coatings, but as plastics they are most frequently used in molding compositions and laminates. The tensile strength of unfilled rigid thermosetting resins is of the same order as for amorphous thermoplastics, that is, about 55 MPa, but this value may be greatly affected by the choice of fillers. For example, polyester–glass chopped-mat laminates often have tensile strengths in excess of 100 MPa, while values several-fold higher may be achieved by using carbon or boron fibers with epoxy resins. Further increases are becoming possible through the use of nanofillers.

**3.31.7.3.1 Phenol–formaldehyde (phenolic) plastics**

The chemical resistance is affected by the type of phenol used, cresols giving the best acid resistance, while xylenols are often used to obtain the best alkali resistance. For chemical-resistant applications, the fillers used in the molding powder and in the reinforcing material in laminates should be inorganic, for example, glass. These resins<sup>7,19</sup> are usually dark in color.

**3.31.7.3.2 Aminoplastics**

In this group, melamine–formaldehyde resins<sup>7,19</sup> with their good heat resistance, scratch resistance, and stain resistance, are usually preferred to urea–formaldehyde resins, where chemical resistance is important. Unlike the phenolics, these materials are not restricted to dark colors.

**3.31.7.3.3 Unsaturated polyesters**

It is possible to prepare unsaturated polyester-based laminates without application of external heat and pressure, thereby facilitating the manufacture of large objects such as boats using simple equipment. The laminates have somewhat limited chemical resistance, being attacked by many acids, alkalis and organic solvents.<sup>7,19</sup> Glass fiber is the common reinforcing agent, and in some products there is a tendency

for capillary action to occur along the fiber bundles. Distilled water, in general, is more active in this respect than aqueous salt solutions, including seawater.

**3.31.7.3.4 Epoxy and furan resins**

These important materials,<sup>7,19</sup> somewhat more expensive than the polyesters, may also be fabricated without the use of pressure, and at ambient temperatures, if so desired. They are markedly superior to polyesters in chemical resistance, particularly towards alkalis.

**3.31.7.3.5 Silicones**

This term is given to a wide range of polymers<sup>7,19</sup> including fluids, rubbers and thermosetting resins. Although rather expensive compared to most other plastics, they are particularly noted for their thermal stability and their water repellency.

**3.31.7.3.6 Polyurethanes**

These are another large class of polymers<sup>7,19,30</sup> that are available in a wide range of forms, including rigid and flexible rubbers, foams, surface coatings and adhesives. The solid polymers, including the rubbers, have particularly good abrasion resistance. The polyurethanes, as a class, are somewhat lacking in resistance to acids and alkalis, and to the prolonged action of water and steam.

**3.31.8 Polymers with Enhanced Heat Resistance**

Very often, a desirable feature of a plastic material is its low softening point which enables it to be melt-processed at temperatures much lower than those normally used for metals and inorganic glasses. The ever-more sophisticated uses to which plastics materials have been put have, however, led to the demand for newer polymers with improved heat resistance to supplement those materials already available such as PTFE and the polycarbonates. For example, the polyimides (e.g., bismaleimides) are a developing class of polymer with good high temperature properties.<sup>7,19</sup>

Factors that need to be taken into account at high temperatures are the flammability of the polymer, or a compound from it, and the smoke evolution characteristics of the polymer and its degradation compounds. In general, the maximum service temperature for which a polymer may be used in a given application (i.e., prior to serious oxidative degradation, including burning) depends generally on two independent factors.

1. The thermal stability of the polymer, particularly in air.
2. The softening behavior of the polymer.

Polymer thermal stability is largely concerned with chemical reactivity, which may involve oxygen, ultra-violet radiation or depolymerization reactions. The presence of weak links and the possibility of chain reactions involving polymer chains may lead to polymers having lower thermal stability than predicted from studies of low-molecular-weight analogues.

The softening behavior of a thermoplastic material depends to a large extent on the flexibility of the chains and their ability to crystallize. Significant cross-linking of a reasonably stiff-chained polymer will lead to material that is unlikely to soften below its decomposition temperature. Intermediate to the linear and cross-linked polymers are various 'ladder polymers' in which the polymer molecule consists of a pair of more or less parallel chains bridged in a manner analogous to the rungs of a ladder.<sup>31,32</sup>

Resistance to burning depends on many factors. It is, however, to be noted that those polymers that burn only in air enriched with oxygen tend to have high carbon-to-hydrogen ratios and/or may also emit materials during degradation, such as hydrogen chloride, which are inherent flame retardants. Low smoke emission is also often associated with a high carbon-to-hydrogen ratio. Table 3 gives some collected data for the limiting oxygen index, the minimum percentage of oxygen in an oxygen/nitrogen mixture that will sustain combustion under a specified set of test conditions.

Polyimides, obtained by reacting pyromellitic dianhydride (1,2,4,5-benzenetetracarboxylic anhydride) with aromatic amines, can have ladder-like structures and commercial materials that may be used up to temperatures in excess of 300 °C are available. They are, however, somewhat difficult to process. Thus, the polyamide-imides, which are easier to process but have lower heat resistance, have been developed. One disadvantage of polyimides is their limited resistance to hydrolysis; therefore, they may crack in aqueous environments above 100 °C.<sup>7,19</sup>

The polyether imides show much better hydrolytic stability with little change in tensile strength after exposure to water at 100 °C for 1 year. These materials also show exceptional resistance to mineral acids and are unharmed by most hydrocarbons including gasoline (petrol) and oils.

Although all commercial polysulfones are, in fact, polyethersulfones, the latter term is given to specific polysulfones that have improved heat resistance.

**Table 3** Limiting oxygen index data for a variety of polymers (unfilled)

<i>Polymer</i>	<i>Limiting oxygen index (%)</i>
Polyacetal	15
Polymethyl methacrylate (Perspex)	17
Polypropylene (PP)	17
Polyethylene (PE)	17
Polybutylene terephthalate (PBT)	18
Polystyrene (PS)	18
Polyethylene terephthalate (PET)	21
Nylon 6	21–34
Nylon 66	21–30
Nylon 11	25–32
Polyphenylene oxide (PPO)	29–35
Acrylonitrile butadiene styrene (ABS)	29–35
Polycarbonate of bisphenol A	26
Polysulfone	30
Polyimide	32
Polyarylate	34
Polyether sulfone (PES)	34–38
Polyether ether ketone (PEEK)	35
Phenol-formaldehyde resin	35
Polyvinyl chloride (PVC)	23–43
Polyvinylidene fluoride (PVdF)	44
Polyamide-imide	42–50
Polyphenylene sulfide (PPS)	44–53
Polyvinylidene chloride (PVdC)	60
Polytetrafluoroethylene (PTFE)	90

Commercial polymers now have values of  $T_g$  ranging from 190 to well above 300 °C, but the cost generally increases sharply with  $T_g$ .<sup>7,19</sup> Polyether ether ketones (PEEKs)<sup>7,19</sup> are similar to polyethersulfones; however, unlike the polysulfones, these materials are crystalline and have higher maximum service temperatures. They also have better resistance to hydrolysis at elevated temperatures than the polyimides. Polyarylates are highly aromatic linear polyesters with relatively high values of  $T_g$  (up to 194 °C) and are self-extinguishing.<sup>7,19</sup>

Polyphenylene sulfides,<sup>7,19</sup> when glass-fiber filled, have high temperature ratings, second only to PEEKs among commercial thermoplastics. These materials often have better resistance to environmental stress cracking than the polysulfones and have found use in automotive applications because of their resistance to corrosive engine exhaust gases, ethylene glycol and gasoline.

### 3.31.9 Thermoplastic Rubbers

These materials<sup>7,19</sup> have characteristics of both rubbers and thermoplastics. At room temperature they

behave like cross-linked rubbers, but at elevated temperatures the cross-links, in the form of separated phases in block copolymers such as SBS (styrene-butadiene-styrene triblock copolymer), or ionic clusters or crystallites, break down and the materials may be processed like a thermoplastic. Unlike truly cross-linked (vulcanized) rubbers, these materials may be capable of dissolution in solvents, although not necessarily at room temperature.

SBS thermoplastic elastomer is a block copolymer consisting of a block of butadiene units end-capped by polystyrene blocks. Below the  $T_g$ , the polystyrene blocks from different chains congregate into polystyrene domains, which act as both cross-links and reinforcing fillers. The polymers will dissolve in certain hydrocarbon solvents. Hydrogenated SBS materials have better resistance to ageing.

Thermoplastic polyester rubbers<sup>7,19</sup> are also block copolymers consisting of polyether and polyester sequences. The polyester groups are capable of crystallization and the crystal structures, in this case, act as the physical cross-links. These materials have good hydrocarbon resistance. Similar thermoplastic polyamide rubbers are also available. Thermoplastic polyolefin rubbers are usually blends based on polypropylene and ethylene-propylene rubbers. They are not resistant to hydrocarbons.

### Glossary

**Extrusion** A manufacturing process in which a softened blank of plastic material is forced through a shaped die to produce a continuous ribbon of the formed product.

**Gelcoat** A polymer material that is used to provide a high-quality finish to the visible surface of a fiber reinforced composite material.

**Polymer resin** A polymerized synthetic or chemically modified natural material including thermoplastic materials such as polyvinyl, and thermosetting materials such as epoxies, that are used with other components such as fillers to form plastics.

**Pultrusion** A manufacturing process that consists of pulling a fiber reinforcing material through a resin impregnation bath and a shaping die prior to final curing.

**Thermoplastic** A polymeric material (for example nylon) which, upon curing, forms one- or two-dimensional molecular structures and is capable of being repeatedly softened by

increases in temperature and hardened by decreases in temperature.

**Thermoset/thermosetting** A polymeric material (e.g., epoxy) which, upon curing, results in a three-dimensional structure and decomposes rather than melting upon heating.

### Abbreviations

**CPI** Chemical processing industry

**CRA** Corrosion resistant alloy

**DCB** Double cantilever beam

**DMA** Dynamic mechanical analysis

**DSC** Differential scanning calorimeter

**ECR** Corrosion resistant e-glass

**ESC** Environmental stress cracking/corrosion

**FRP** Fiber reinforced plastic

**FTIR** Fourier transform infrared

**GC** Gas chromatography

**GRP** Glass reinforced plastic

**MS** Mass spectroscopy

**TGA** Thermogravimetric analysis  
**TMA** Thermomechanical analysis  
**UV** Ultraviolet  
**Vf** Fiber volume fraction

## Symbols

**c** Chlorine dioxide concentration ( $\text{g l}^{-1}$ )  
**t** Time (s)  
 **$T_g$**  Glass transition temperature  
 **$t_{95}$**  Time to reach 95% of original property (s)  
**B** Factor in the presence of deposits  
**D** Diffusion coefficient ( $\text{m}^2 \text{s}^{-1}$ )  
 **$E_a$**  Activation energy ( $\text{J mol}^{-1}$ )  
 **$E_{11}$**  Young's modulus in the fiber direction (GPa)  
 **$E_{22}$**  Young's modulus transverse to the fiber direction (GPa)  
 **$G_{12}$**  Shear modulus (GPa)  
 **$M_t$**  Total mass absorbed at time t (kg)  
 **$M_\infty$**  Total mass at equilibrium (kg)  
**R** Universal gas constant ( $\text{J K}^{-1} \text{mol}^{-1}$ )  
**T** Temperature (K)  
**W** Rate of weight loss ( $\text{kg s}^{-1}$ )  
 **$\alpha$**  Corrosion depth factor  
 **$\Phi$**  Depth of corrosion (m)

### 3.32.1 Introduction

In the past, the primary reason for the use of fiber reinforced plastics (FRPs) is because of weight saving

for their relative stiffness and strength. As an example, a carbon fiber composite can be five times stronger than 1020 grade steel while having only one-fifth the weight. Aluminum (6061 grade) is much nearer in weight to carbon fiber composite, but the composite can have twice the modulus and up to seven times the strength. A comparison of some properties of metals and composites is shown in **Figure 1**.

A composite, which is generically a material that is made up of two or more distinct (i.e., macroscopic, not microscopic) materials, comes in different configurations but is essentially a plastic material within which there are embedded fibers or particles. The plastic, or more correctly a polymer, is more often termed the matrix or sometimes the resin. The fibers or particles dispersed within the polymer are known as the reinforcement. The reinforcement is generally orders of magnitude stiffer than the matrix, thus resulting in a stiffened plastic. This stiffer reinforcement can either be randomly distributed short fibers or continuous fibers (sometimes in mat form) that are laid in a particular direction within the matrix. The resulting material thus may have different properties in different directions (anisotropic or orthotropic, depending on the lay-up). This characteristic is usually exploited to optimize the design and results in the composite material being tailorable in that its mechanical properties can be formed to meet specific directional loading.

Most engineering materials are essentially isotropic. That is, they have the same properties such as strength and modulus in any direction. There may be 'grain' in some metals because of the manufacturing

**Figure 1** Comparison of specific strength of different metals and FRPs ([www.merl-ltd.co.uk](http://www.merl-ltd.co.uk)).

process, but it is only in critical applications that this matters. Most machining or casting processes do not have to take directional differences into account. Because of the different fiber orientation, mentioned above, most composites will have very different properties in different directions. For example, a carbon FRP may be up to 100 times stronger under tension than it is in shear, and the stiffness may differ in the two directions by similar ratios.

Several different terms have been used by different industries to describe a composite material, and these acronyms have become jargons. More technical descriptions include:

GRP	Glass reinforced plastic (in which the fiber is glass and the resin is any of the polymer resins)
GRE	Glass reinforced epoxy (in which the fiber is glass and the resin is an epoxy)
FRP	Fiber reinforced plastic (in which the fiber may be any of those listed above and the resin is any of the polymer resins)
CFRP	Carbon FRP (in which the fiber is carbon and the resin is any of the polymer resins)
PMC	Polymer matrix composite

None of these terms are incorrect, although some cover a wider range of material classes. FRP is a generic term and will be used throughout this chapter when referring to composite materials generically.

Both thermosetting and thermoplastic polymers can be used for the matrix material, and the most common thermosetting matrix materials include polyester, vinyl ester and epoxy, and bismaleimide for higher-temperature applications. Thermoplastic matrix materials tend to have higher performance ability and include polymers such as polyimide, phenolic, polypropylene, polyetheretherketone (PEEK), and polyphenylene sulfide (PPS).

Another primary benefit of FRPs is their durability in hostile environments, often termed corrosive environments, although in reality, composite materials do not 'corrode.' While the matrix is primarily the binder that transfers the load to the reinforcement, it is also very resilient to environmental attack. The type of resin needs to be carefully selected so that it can withstand the service temperature (high or low) conditions, and it should not be significantly affected within its lifetime by fluids (gases or liquids) with which the FRP will come into contact. Hence,

FRPs are used in very corrosive applications such as for acid storage in the chemical processing industry and longevity in marine environments such as in vessels and offshore oil and gas applications. These applications are discussed in more detail in this chapter.

The effect of exposure to various environments such as heat, moisture, solvents, acids, ozone, hydrocarbons, loads, etc., and more importantly a combination of these parameters, may degrade the material's key properties. For load bearing applications, these properties may include stiffness and strength. Cracks may appear and accumulate ultimately leading to failure. For fluid containment applications, cracks may coalesce leading to a leak path for this fluid even though the structure is globally still intact. Despite these safety critical uses, the degradation of an FRP is still not a well understood phenomenon compared to the corrosion of metals.

The reason that the long-term degradation of FRPs is not well understood is because it is a very complex process with many interrelated factors and has led to much ongoing research into the topic. Degradation is often given the generic term 'ageing' that can include the more benign physical ageing effects such as swelling from moisture absorption, that is largely reversible, to the more serious chemical ageing where material properties are permanently (irreversibly) degraded. Additionally, synergistic effects to ageing from mechanical loading, such as creep, need to be considered in isolation (or in addition) to that associated with the environment and often change the rate of degradation. Environmental ageing of FRPs occurs from the surface or edge inwards and requires time to penetrate into the material's center, and the rate of ageing can be directional (like the mechanical properties); further, it is generally dependent on the temperature and stresses. The complexity described above makes predicting ageing around detailed geometries such as stress concentrations nontrivial.

Added to the issue of ageing of FRP materials is the variety of different manufacturing methods available to manufacture components. The reader is pointed toward the works of Jones,<sup>1</sup> Matthews *et al.*,<sup>2</sup> and in ASM Handbook<sup>3</sup> for detailed information on manufacturing. The methods available depend very much on the nature and quality of the component to be manufactured. For the low-end marine industry, uncured resin is poured over chopped glass fibers laid in a mould to form what is often termed 'fiberglass.' A step-up on this approach is known as filament

winding where the fibers are wrapped around a net-shape mandrel, and the resin poured on or the fibers are dipped in the resin before winding. Both methods are low-cost manufacturing techniques and the resin is generally cured at room temperature. Alternative lower-cost manufacturing methods include injecting the resin into a mould or extruding or pultruding the composite profile through a die to form the part desired. Additionally, resin-rich layers, known as gel coats can be put on the outside of the parts for better resistance or appearance. To improve the quality and performance of the resin, vacuum, pressure and temperature are used in a variety of combinations. A vacuum is employed by placing the component in a bag and the vacuum is used to help to pull the resin through the fibers and, more importantly, to remove air and other gases from the final composite part reducing porosity. Pressure is used on the outside of the vacuum bag to help form and consolidate the part again, helping to reduce porosity. Temperature is used for stronger resins to assist in curing and consolidation. The combination of these three manufacturing parameters requires an autoclave and produces a high-quality, high-strength part and is still the manufacturing method of choice for the aerospace industry.

A further difficulty is introduced with the need to predict long-term ageing using short-term testing and analysis. For long-term life prediction based on short-term data, representing the true service history (load, temperature, time, fluid, etc.) for long-term structural life prediction is a vital step to validate any short-term-based predictive methodology. The coupon tests must reflect the effect of ageing on the polymer (i.e., matrix-dominated properties) because the fibers may mask any property loss in the resin. However, fibers can sometimes degrade in some environments quicker than the polymer and additionally the fiber–matrix interface can be attacked and this too must be represented in any accelerated ageing methodology. Further, the chemical bond between the fiber and resin itself (often known as the interface region) can be degraded. All of these degradation methods are important to understand. Loss of fiber properties greatly reduces the strength and stiffness of the FRP laminate because that is their main purpose. Similarly, a break down of the bond between the fiber and the resin leads to the fibers not providing stiffness and strength through transfer of shear between the two. Reduction of properties of the resin is also important because it provides the load transfer between fibers.

It is this shortage of long-term data or of an accelerated ageing methodology to determine the

residual properties of a FRP component at any time in its life that still hinders the uptake of FRPs in some applications. However, over the decades when composites have been used, much has been learned, and this chapter addresses some of this work detailing the nature of ageing of composites and the use of composites in certain industry sectors where corrosion or degradation is an issue. This chapter will describe how it is the degradation or ageing of a composite that needs to be understood when these materials are used in hostile environments. This chapter is not intended to be a general introduction to FRPs; there are many publications available for this purpose<sup>1–3</sup> or informative internet-based sites such as The Virtual Composite Material Consultant.<sup>4</sup>

### 3.32.2 Ageing Mechanisms

The ageing of an FRP comprises an ongoing development of damage that is dependent on the type of polymer matrix, the fiber type and architecture, the fiber volume fraction and the operating conditions of temperature, relative humidity, oxidative attack, solvent infusion, internal moisture concentration, air pressure, mechanical loads, and the time of exposure. These degradation factors are often related and varying. For example, a FRP pipe used to transport hydrocarbons may experience hot oil field fluids internally, ultraviolet (UV) radiation from sunlight, and moisture externally, external loads from supports and other loading. The external temperature may vary between  $-40$  and  $+40^{\circ}\text{C}$  depending on the location while the internal temperature may be that of the oil at temperatures up to  $+100^{\circ}\text{C}$ . However, a fuselage or wing FRP structure may experience temperature cycles of  $-55$  to  $+40^{\circ}\text{C}$  between flight and ground with ice, cleaning solutions, moisture, jet fuel, ozone, UV and other environmental conditions, making the determination of residual life a complex procedure. Therefore, ideally these conditions must be represented in any simulation of ageing for predictive purposes to accurately reproduce the degradation mechanisms. In reality, only the key conditions considered to be the more potentially damaging may be investigated. In any test program, it is important to use relevant material or structural properties as an indicator of the state of ageing of the material. This may be the mass change, the glass transition temperature  $T_g$ , the crack density, the modulus, strength or a combination of these properties. Therefore, a complete understanding of all the degradation processes should be known or an

assumption made on what is the primary degradation mechanism. The section below describes some of the key degradation mechanisms that individually or combined form the ageing of a composite material.

### 3.32.2.1 Physical Ageing and Time-Dependent Effects

Polymers, both in their rubbery (above  $T_g$ ) and in their glassy state (below  $T_g$ ), are characterized by viscoelasticity, a time-dependent mechanical behavior. The characteristic times of this constitutive behavior are much longer in the glassy state and decrease at temperatures near and above  $T_g$ . Typical evidences of viscoelasticity are creep and stress relaxation. Creep is a time-dependent deformation that usually has three stages when under a constant load, rapid primary creep, a steady-state secondary creep rate and a rapid acceleration in the creep rate leading to rupture. Stress relaxation is a related phenomenon where stresses are relieved when under a constant deformation. In composite materials, the stress transfer between the viscoelastic matrix and the elastic reinforcement, or between layers with different fiber directions (laminae) needs to be considered for long-term ageing characterization. For long-term property estimation, especially when considering FRP properties that are more dominated by the resin than the fiber, long-term viscoelastic behavior can be accelerated by adopting the time-temperature superposition principle.<sup>5,6</sup> This principle is based on the premise that the behavior for long time periods at low temperatures corresponds to that for short time periods at higher temperatures. This is because in a polymer, the polymer chains are more mobile and easier to arrange at higher temperature resulting in a higher compliance or lower modulus. The time-temperature superposition principle is evident from the compliance curves in creep experiments (or modulus curves for stress-relaxation experiments) at different temperatures that are related to one another by a simple temperature-dependent shift on the log time scale.

The fundamentals on physical ageing and the dependency of mechanical properties on time and temperature become more pronounced when testing close to the  $T_g$ . The  $T_g$  itself may well be affected by moisture; lowering  $T_g$  and service temperatures may be close to wet  $T_g$  requiring aspects of physical ageing to be a vital part of a durability analysis.

With physical ageing, polymers below their  $T_g$  exhibit a time-dependent rearrangement of their

structure. The mutual interaction between viscoelasticity and physical ageing imposes the introduction of time-ageing and time-temperature shift factors. Other time-shifting effects may also exist based on the applied stress, moisture condition and other environmental factors. These time-dependent properties and physical ageing has an affect on the material's overall strength and stiffness. Thus, ideally an accelerated ageing analysis needs to include an aspect of physical ageing such that the strength/failure criteria includes time-dependent coefficients and a nonlinear viscoelastic-viscoplastic damage analysis.

For accelerated physical ageing tests, the relationships are obtained from short-term tests using the time-dependent experimental data described above. It is important that no chemical ageing (discussed further below) is included. The typical properties measured depend on the application, but most testing presented in the literature has been on off-axis plies because they give a good representation of matrix-dominated properties.<sup>6</sup> However, the literature often falls short in producing such time-dependent relationships for more useful design properties such as static properties of FRP laminates with or without holes.

### 3.32.2.2 Hygrothermal Effects

Hygrothermal effects are related to the uptake of water molecules from a humid environment or water in direct contact with the FRP when the component is submerged in water (or other solution). The water is absorbed by the polymer matrix and results in plasticization of the matrix leading to hydrolytic degradation or hydrolysis which lowers the molecular weight and hence mechanical properties of the FRP. The rate of hydrolysis may be accelerated by the application of load or more significantly with elevated temperature and high- or low-pH conditions. In contact with the polymer, low molecular weight liquids are absorbed by and diffuse into the polymer until saturation (equilibrium) is reached. The rate of diffusion and equilibrium are dependent on the chemical structure and morphology, such as the degree of crystallinity of the polymer. For an FRP, these properties are also related to the type of fibers, the volume fraction and the nature of the fiber-matrix interface.

The relationship between time and moisture mass uptake can classically be characterized using simple approaches such as Fick's law, but generally for FRPs, diffusion is more complex with competing factors affecting the rate of diffusion.<sup>7</sup> With time, moisture diffuses into the FRP through the surfaces and there

is a moisture-content concentration gradient through the thickness. Indeed, for some FRPs there may be a different concentration through the edges than through the surfaces. If the moisture content or temperature is cycled, this will lead to local dryness at the surface plies compared to the centre of the laminate. This moisture distribution can lead to significant residual stresses within the laminate that can in turn cause outer ply delamination of blisters.

Short-term hygrothermal effects on FRPs may extend beyond plasticization of the matrix and lead to mechanical damage such as the creation of microvoids, matrix cracking and blistering. These microcracks, in turn, provide fast diffusion paths (for both liquid water and water vapor) and then alter the moisture-absorption characteristics of the laminate.

Long-term exposures may not cause mechanical damage, described above, but the plasticization may well change matrix-dominated mechanical properties such as interlaminar and intralaminar shear modulus and the transverse tensile strength and modulus. Properties like compression modulus and strength are greatly affected by the shear properties of the matrix; hence, under hot and wet conditions compression properties may be severely degraded. The high temperature and humidity exposure of FRPs effectively plasticizes the matrix, more so closer to the  $T_g$  of the material which reduces when the material is saturated.

Post-cure reactions, hydrolysis and leaching of products within the FRP coupled with the decrease of  $T_g$  when moisture is absorbed, make modeling the effects of moisture complex and warrant further investigation. Such modeling can supply important information to establish the effects of moisture on time-temperature shift factors, by scaling the temperature axis on the basis of  $T_g$  change. As a result, Fick's law needs to be extended to model three-dimensional diffusion in anisotropic materials. For FRPs, the value of the diffusion coefficient,  $D$ , for the neat polymer needs to be modified to account for the tortuous path created by the presence of the fibers (their size, distribution, aspect ratio, orientation, etc.). Hence,  $D$  becomes an anisotropic property that is dependent on fiber direction. In FRP laminates with several layers of different orientation, the different diffusivity in each layer must be considered for the overall laminate. In ideal Fickian behavior, moisture absorption increases linearly with the square root of time for values of  $M_t/M_\infty \leq 0.5$  (where  $M_t$  is the total amount of moisture absorbed at time  $t$  and  $M_\infty$  is the total amount absorbed at equilibrium). Time-thickness scaling allows the long-term prediction

of absorption in thick laminates from thin-sample measurement, when Fick's law applies. Diffusion can be accelerated by increasing the temperature and follows the Arrhenius relationship eqns [1]

$$D = D_0 \left[ \exp \left( \frac{-E_a}{RT} \right) \right] \quad [1]$$

Where  $E_a$  is the activation energy of the diffusion rate,  $R$  is the universal gas constant, and  $T$  is the absolute temperature of the exposure in Kelvin.

As discussed above, Fickian law may not always be demonstrated in composites where, following reaching equilibrium, there can be a slow long-term increase in mass uptake or a decrease in mass or both. The decrease may arise from products leaching from the FRP over time and the increase from a two-stage absorption process where the first is Fickian and the second a relaxation-based phenomenon.<sup>8</sup>

### 3.32.2.3 Thermooxidative Degradation

While the application of temperature and moisture can have negative effects on the composite, exposure to temperature in an air environment can cause thermooxidative ageing. This ageing mechanism arises from the thermal instability of the polymer and leads to oxidative attack that comprises chain scission, cross-linking, and thermooxidative reactions. Thermal degradation of FRPs, in an inert atmosphere, is exclusively a thermolysis phenomenon, while in air it is dominated by oxidation. Thermolysis is the result of breaking of covalent bonds in the polymer network and, in general, thermal stability of high-performance polymers in an inert atmosphere is very good.<sup>6,8-11</sup> Oxidation is usually characterized in terms of weight loss generally from the surfaces of the laminate. This weight loss is predominantly from the matrix and will penetrate into the laminate at higher temperatures and long exposures. Eventually, microcracks will form leading to a larger reduction in the mechanical properties of the FRP. These weight losses are generally permanent (irreversible) and even a small weight change can be an indication of the onset of damage at the surface. For oxidation to occur at the center of the laminate, the diffusion process must be understood, including the diffusion of oxygen and reactions products throughout the polymer matrix in a similar manner to liquid diffusion discussed above. The pattern of oxidation reactions and subsequent chemical changes depends on the exposure temperature, the resin system, and the oxygen content. Simply

increasing the temperature to accelerate the characterization of oxidation is nontrivial. The changes in mechanical properties postexposure are a function of sample thickness and surface protection as well as the ageing temperature and the material's  $T_g$ . Therefore, the examination of the thermooxidative stability of an FRP must include not only the degradation of mechanical properties, but also the failure mechanisms to ensure that they are consistent when comparing two laminates aged at different temperatures in an attempt to accelerate thermooxidative ageing.

#### 3.32.2.4 Chemical Ageing

Chemical ageing follows principles very similar to oxidative ageing but occurs when the environmental fluid is an acid, alkali solvent, or many other fluids to which an FRP may be exposed. These chemicals actually attack the resin, the fiber, or the fiber–matrix interface (or any combination of these three). When the FRP is subjected to exposure to, for example, an acid solution, depending on the concentration of the solution, competing ageing mechanisms may occur. The liquid will first be absorbed in a hygrothermal fashion as described above. In time (dependent on the strength and nature of the chemical involved and the compatibility of the polymer), the material will chemically react with the FRP. This results in an increase in cross-linking density that can severely affect the mechanical properties by densification and increasing the  $T_g$ . Also, products may be leached out of the FRP in an irreversible manner. This will result in weight loss and a potential decrease in properties. With further time, actual physical material loss can occur, resulting in a more dramatic change in properties.

In order to perform studies of long-term and accelerated chemical ageing, usually a large test program is required with long periods of time and a selection of parameters (temperature, chemicals, loads). A variety of specimen types is also required to assess the degradation of mechanical properties parameters such as specimen type, lay-up, thickness, material, etc. As with other ageing types, chemical ageing is a diffusion-related phenomenon. Therefore, the use of thick specimens will delay observable changes in mechanical properties although significant surface damage may have occurred. Different lay-ups will affect the interlaminar stresses, which will affect diffusion rates.<sup>12</sup> Additionally, edge effects can play a role and this is often where mechanical failure can initiate. As a result, chemical ageing exposures are often conducted on panels of FRP and mechanical specimens cut from

these panels once the ageing is complete. Another approach is to coat the free edges of the test specimens with a resilient coating to prevent unrepresentative edge damage.

An additional approach to characterizing chemical ageing to better understand the change in the polymer is to conduct thermal analysis on the FRP or the matrix. Of all the properties,  $T_g$  is the most common one measured using thermal analysis because it is a good indication of physical changes. Methods and approaches to measure  $T_g$  vary and all are reasonably well established as standards. These include dynamic mechanical analysis (DMA) that may be performed in torsion or flexure depending on the test apparatus; differential scanning calorimetry (DSC); or thermomechanical analysis (TMA). These methods all raise the temperature of the FRP and look for inflection points of peaks in the property being measured. The DMA tends to be more sensitive than the DSC for materials such as phenolics. Thermogravimetric analysis (TGA) is used to measure the rate of change of weight versus time and temperature in a controlled gas environment. TGA is highly dependent on the available surface of the specimens placed into the test chamber and hence the size of the pieces of materials that are used can effect measurements. It is sometimes useful to identify how the polymer has changed during ageing and other equipments such as Fourier transform infrared (FTIR) spectroscopy and gas chromatography (GC) as well as mass spectroscopy (MS) are used to evaluate the degradation products. These techniques can also be used for thermooxidative ageing.

#### 3.32.2.5 UV and Weathering Degradation

Similar to oxidative ageing, weathering affects the surface of the FRP laminate. Generally, UV ageing affects the appearance of the laminate (particularly color loss) and this degradation in appearance can be considered failure (aesthetically). Often, the change in color has a minor effect on structural performance. Weathering is a combination of ultraviolet radiation, temperature from the sun, oxygen and any ambient moisture such as humidity or precipitation.<sup>13,14</sup> With the use of coatings and additives, the structural performance of FRPs can be maintained and the weathering effects tend to be surface related and appear as:

- fading and darkening;
- yellowing;
- blooming; and
- loss of gloss and chalking.

Yellowing, fading, and darkening are generally due to chemical degradation in the polymer. Blooming can be caused by an additive coming to the surface, whereas loss of gloss is generally caused by erosion of the surface layer. While the loss of surface quality may be considered benign, it can lead to leaks and weakening.

The severity of the ageing due to weathering is strictly dependent on the nature of the climate or the geographical region, for example, tropical, desert, arctic, etc. Predicting the weathering performance of FRPs is carried out both in laboratories using artificial weathering and in long-term experimental field ageing. The latter takes several years and becomes very specific to the material and location selected for the study. The specimens are directly exposed to outdoor conditions at a fixed angle relative to the horizontal and in a fixed direction. To accelerate weathering, the UV radiation is concentrated onto the test specimen using special mirrors. Also, locations with high levels of sunshine, for example, Florida and Arizona are used to compare with longer-duration exposures in regions with less sunshine hours.

There are a larger number of laboratory-based ageing tests along with actual case studies where specimens are exposed to UV radiation from a variety of UV light sources. There are currently three key laboratory methods used for artificial weathering.<sup>14</sup> The carbon arc lamp uses two strong emission bands that peak at 358 and 386 nm which are much more intense than natural sunlight. These have a lower effect than solar radiation on materials that absorb only short-wavelength UV radiation. The xenon arc lamp gives a broad spectrum of light that matches the solar spectrum quite closely. Filters are used to reduce the short-wavelength UV light from these lamps that are not present in sunlight. Fluorescent lamps have special phosphors selected to emit UV light at a particular waveband. Exposure is carried out under controlled conditions of temperature and moisture. With the varied nature of weather, conducting accelerated tests to simulate specific weather exposure for predictive purposes is difficult. As a result, accelerated methods tend to focus on the worst-case weather scenarios and any correlations must be qualitative.

### **3.32.2.6 Mechanical Degradation**

This chapter focuses more on the ageing of FRPs under environmental loads, and, strictly speaking, mechanical degradation is not part of ageing. Nevertheless, it is often a consequence of ageing. Mechanical damage processes such as matrix cracking, delamination, plastic strain,

interfacial failure are generally irreversible. In an FRP, some of these damage modes may be seen to be benign or subcritical; however, the damage may accumulate or lead to damage elsewhere by transferring load ultimately leading to failure. The most common mechanical degradation, especially when operating at high temperature, is the formation of cracks in the matrix either within the ply or transverse to the ply. Fatigue, environmental loading, and residual stresses can all promote the onset and accumulation of these cracks. The laminate strength, stiffness, and thermal properties as well as failure modes can be affected by transverse matrix cracking which can also promote higher uptake of moisture deeper in the laminate. The prediction of these failure modes are often parts of a long-term durability assessment, especially under fatigue loads. The reader is directed towards Jones,<sup>1</sup> Mathews and Rawlings,<sup>2</sup> and ASM Handbook,<sup>3</sup> for a description of predicting mechanical failure in FRP laminates.

### **3.32.2.7 Fire Testing**

While the above sections discuss various environmental forms of ageing, FRPs are often, perhaps surprisingly, used in high-risk fire applications. These include the aerospace industry in the event of on-board fires and crashes, marine vessels with very high requirements for resistance to fire, railways, where the fire resistance for underground trains is perhaps the most stringent, and offshore oil and gas requirements. Many of these fire-resistance requirements arise from unfortunate incidents. Glass and carbon fibers do not burn but the resin may well set alight or give off noxious fumes or both. Different resins have different fire resistance to jet fires (where a flame is concentrated on one spot) and pool fires. The combination of low thermal conductivity, resin endotherm effects, structural integrity and coatings mean FRPs can have excellent fire-resistance performance but this does need to be strictly controlled using established small-scale tests to evaluate the combustibility and ignitability. Models based on the energy flux involved in decomposition have been used to predict fire performance of materials.<sup>15</sup> However, no further discussion on fire testing is given in this chapter because it goes beyond the scope of less severe forms of ageing and degradation.

### **3.32.2.8 Synergistic Effects**

Each of the sections above described individual possible ageing mechanisms that may occur to an FRP

laminate. However, an FRP component is a combination of fibers, the fiber–matrix interface, and the polymer matrix that may be subject to long-term ageing of a combination of the above ageing scenarios. Hence, the mechanical properties and fitness for purpose may change through a combination of thermal oxidation, physical ageing, hygrothermal effects, UV exposure, and chemical attack. Therefore, macroscopic changes need to account for the synergies between these ageing mechanisms and any accelerated ageing methodology should really account for these combined factors – a nontrivial task!

### 3.32.3 Accelerated Ageing

As discussed above, one of the biggest advantages of composite materials is their long life in harsh environments. Ironically, it is this long life and the difficulties in being able to reliably predict the long life that has hindered the uptake of composites. The development of a robust accelerated ageing methodology is a key technology development for FRPs. An accelerated-ageing methodology should accelerate the action of degradation factors without altering the underlying molecular mechanisms of ageing. The analogy that a chicken does not hatch quicker from the egg by boiling the egg applies here. As discussed, the ageing process may cause both reversible and irreversible changes and the accelerated ageing methodology must simulate these processes. The design of an accelerated methodology relies on the knowledge of material properties and their relationship with environmental conditions (temperature, pressure, loads, relative humidity, UV, etc.) and upon the fundamental ageing or damage mechanisms as described in the previous section.

The purpose of accelerated ageing methodology is simply to speed up the accumulation of damage or deformation, potentially leading to failure. This is achieved by establishing relationships between time and various parameters, such as temperature, fluid concentration, load, etc. that can be related back to the in-service conditions. Accelerated testing also aims to determine the material microstructure and damage at the end-of-life or ideally at any time during the life of the component. For most structural applications, the durability and mechanical fatigue are the main degradation processes in which frequency and load are the main acceleration factors used. For FRPs in corrosion applications, exposure temperature is the primary means of accelerating

ageing, but other parameters include increasing the concentration of a degradative chemical, applying pressure, or a load. Most accelerated ageing experiments consider a single accelerating factor because it is difficult to test multiple accelerated conditions and understand the synergistic effects as discussed above. The preferred approach is to incrementally subject samples to accelerated conditions. For the approach to be valid, a fundamental understanding of material response and the reversible and irreversible degradation processes is required and needs to be incorporated into the modeling.

An accelerated test methodology must follow the following steps<sup>16</sup>:

- (a) identification of the material, including the polymeric matrix and the fiber (including type, volume fraction, orientation, sizing, etc.);
- (b) identification of the primary ageing mechanism for the environment, for example, thermooxidation, hydrolysis, UV ageing, etching, . . .;
- (c) identification of the physical properties, most important to the application, to be measured in the accelerated ageing test (e.g., mass loss, stress, strength, toughness, leak resistance, color, . . .);
- (d) selection of the environmental acceleration of degradation factors such as temperature, time, concentration, etc.;
- (e) carry out the accelerated tests under conditions given in (c) and (d);
- (f) use theoretical modeling (e.g., Arrhenius relationship, time–temperature superposition, curve-fitting) of the degradation factors; and
- (g) validating some of the modeling by performing long-term tests that are representative of in-service conditions.

For accelerated ageing, the synergistic effects of time, pressure, and conditions on FRP degradation should be established. Free space exists between molecular chains to a greater or lesser degree leading to a balance between stiffness and flexibility. However, this same free space can mean that polymers can absorb fluids to which they are exposed, especially those with similar solubility parameters. Such absorption can physically weaken the polymer to provide an effect of ageing. In addition, the fluid might chemically attack the polymer to provide an additional effect. The kinetics of these two ageing effects is governed by; (i) diffusion, and (ii) chemical kinetics, both of which are governed by Arrhenius relationships with regard to the influence of temperature. This characterization is commonly based on

weight loss and, where possible, mechanical property reduction measurements as a function of time and temperature. The rate of weight loss ( $W$ ) versus time can be modeled by using an Arrhenius relationship, eqns [2].<sup>8</sup>

$$W = A \left[ \exp \left( \frac{-E_a}{RT} \right) \right] \quad [2]$$

where  $W$  represents the ratio between the weight loss and the starting weight of the sample and  $A$  is an empirical factor. However, because the thermooxidative degradation in an FRP laminate occurs at the surface, the above equation does not necessarily relate to the same reduction in mechanical properties that are dominated by the bulk properties, and not just the surface properties. A good example of this is an interlaminar fracture test such as the double cantilever beam (DCB)<sup>17</sup> where the fracture data are measured from a delamination in the centre of the specimen. During an ageing test, much of this delamination is not exposed to the environment.

There are few published works on experimental work using a change in a specific mechanical property of relevance, say modulus or strength in eqns [3], to allow modeling of the global effect on a component from local ageing degradation at the surface. Chemical kinetics, classically involving concentrations of reactants and products, can employ the fact that for cross-linked polymers, concentration of cross-links is approximately proportional to the modulus or stiffness. Hence, measurements of changes in modulus from ageing can be plotted logarithmically against linear time (for first-order reactions) at each temperature. From a series of such ageing plots at different temperatures, times to attain the same degree of modulus change can be used to develop the Arrhenius plot, eqns [3].

$$\ln \frac{1}{t_{95}} = A \frac{-E_a}{RT} \quad [3]$$

where  $t_{95}$  is the time for a property to reach 95% of its original value (although other values can be used),  $T$  is the absolute temperature,  $R$  is the universal gas constant ( $8.314 \text{ J deg}^{-1} \text{ mol}^{-1}$ ),  $A$  is a constant, and  $E_a$  the activation energy. This expression holds well where there is only one degradation mechanism taking place and this is seldom the situation in the chemical processing environments.

The mechanics and chemistry of degradation can be different at higher-temperature exposures to that at lower-temperature exposures. Mass-loss curves can change significantly with temperature because

of different mechanism occurring, including removal of volatiles, additional cross-linking, and structural rearrangements of the matrix. Testing at temperatures too close to the  $T_g$  gives degradation rates that are nonlinear, making estimates of useful remaining life invalid.

One acceleration method for thermooxidative stability is to increase the temperature and the pressure of the oxygen,<sup>18</sup> thus accelerating the rate of degradation due to oxidation. However, other attempts to accelerate ageing in acids by increasing the acid concentration were less successful, with only small increases in the ageing rate being achieved.<sup>19</sup>

While the above sections have described the current technology and gaps in predictive methodologies, there are FRP components in-service with long duration lives. The approaches used to give some estimation on long-term life include single-point data (properties after a specific set of ageing conditions) and short-term ageing extrapolation. The following section describes some applications where ageing has been considered.

### 3.32.4 Ageing Associated with Supersonic Flight

Many of the earliest applications of carbon FRPs were in military aircraft where the main ageing mechanisms were hygrothermal. As discussed above, this reduced the modulus of the matrix lowering some mechanical properties. As a result, most aircraft with FRP components use hot wet properties as part of the design allowables. Several aerospace programmes have been concerned with commercial supersonic aircraft to replace the Concorde. Long-term thermooxidative ageing became a key technology development for these aircraft. The first major study on ageing of FRPs for supersonic aircraft was performed by Kerr and Haskins.<sup>20</sup> The materials investigated included carbon- and boron-epoxy and carbon polyimide that were exposed to elevated temperatures for up to 50 000 h. The effect of altitude was also included representing the reduced oxygen levels at high altitudes. The laminates used were typically  $[0^\circ/\pm 45^\circ]_s$  and temperatures ranging from 122 to 177 °C representing temperatures up to Mach 2.4 flight. The tests performed included tensile, compression, and shear and also tests to study the effects of moisture and creep after the exposures in an attempt to identify the thermooxidative ageing mechanisms. These tests were chosen as those

typically used in an aircraft design process as opposed to those required to identify the effects of ageing.

For some materials, edge cracking and severe property degradation was identified at temperatures of 177 °C after 5000 h of ageing with a 0.1 MPa pressure. This degradation was not noted after 25 000 h at the same temperature but at 0.014 MPa. Degradation was observed for epoxy specimens at times under 5000 h when aged at 177 °C, which was close to the  $T_g$  of materials. Degradation was a severe crumbling of the matrix at the specimen surface. Ageing damage was far less at 122 °C after many more hours exposure. This demonstrates that raising the temperature to accelerate ageing may not be a valid approach when the exposure temperature reaches  $T_g$ . The polyimide-based specimens had much better thermooxidative stability. At 232 °C, after 50 000 h the tensile properties decreased, although no macroscopic damage to the resin could be observed, although clearly some degradation had occurred from the weight-loss results. In this instance, the selection of a matrix-based mechanical test during the ageing program would perhaps identify matrix degradation after shorter exposure times.

During NASA's High-Speed Research (HSR) programme in the 1990s, studies were conducted that focused mainly on high temperature polymers for a new generation of High-Speed Civil Transport (HSCT) aircraft with a speed target between Mach 2.0 and 2.4 with a design requirement of 60 000–120 000 h. The work in this program focused on new materials' development for high temperature use and included carbon bismaleimides and polyimides.

One of the primary difficulties in characterizing the effects of ageing on changes in structural properties is the correlation of 'ageing'-related data, such as weight loss, to changes in material mechanical properties such as strength, stiffness, and toughness. An investigation in the change of lamina properties ( $E_{11}$ ,  $E_{22}$ , and  $G_{12}$ ),  $T_g$  and weight loss for this programme can be found elsewhere.<sup>20</sup> An IM7/8320 carbon thermoplastic and an IM7/5260 carbon bismaleimide were aged in air-circulating ovens at 125 and 175 °C for 5000 h (representing 10% of the life of proposed life for HSCT). In this time frame, the materials showed little signs of ageing at 125 °C. The IM7/5260 had a 2% weight loss after 5000 h at 175 °C. This corresponded to a 10% decrease in  $E_{22}$  and a 2% decrease in  $G_{12}$ , but no significant change in  $T_g$  or  $E_{11}$ .

A test program to evaluate the synergistic effects of stress, temperature, moisture, time, radiation, and oxygen level on the properties of bismaleimide

composites was conducted as part of the HSR programme.<sup>10,11,18,21–23</sup> Isothermal ageing as well as thermal cycling, and creep tests were conducted at temperatures up to 250 °C. As for the Kerr and Haskins work, exposure temperatures close to the materials  $T_g$  led to very rapid ageing and anomalous effects that made it difficult to develop an accelerated ageing approach.

Martin<sup>17</sup> has investigated the delamination onset under thermal mechanical fatigue with modeling used to predict delamination onset. To verify the methodology, isothermal statics tests were conducted at temperatures of 125 and 175 °C (representing Mach 2 and Mach 2.4 flight, respectively) on quasi-isotropic laminates fabricated from carbon bismaleimide (IM7/5260). Raising the temperature had the effect of decreasing the value of strain energy release rate ( $G$ ) at the edge by reducing residual thermal stresses. However, the materials fracture toughness was also lower at higher temperatures. The isothermal ageing results of these materials discussed by Kerr *et al.*<sup>20</sup> would need to be incorporated as additional effects of ageing. These would need to be included in addition to the change in properties related to temperature and fatigue.

For aerospace applications, open-hole tension and compression of laminates are important properties for damage tolerance designs. As discussed above, thermooxidative ageing attacks the surface and an investigation was conducted by Morgan *et al.*<sup>22</sup> to determine the influence on isothermal ageing of laminates with a hole drilled before and after ageing and edge cut before and after ageing. Quasi-isotropic laminates fabricated from IM7/5260, IM7/8320, and IM7/K3B a carbon polyimide added to the HSR program were aged at temperatures of 125 and 175 °C (additional exposures at 200 °C were carried out on the IM7/K3B) for periods up to 5000 h. For IM7/5260 and IM7/8320, significant damage was seen on the surfaces and this degraded the stress to cause delamination at the edges but did not affect ultimate strength of the laminate, because of the presence of 0° fibers in the loading direction. Removal of these damaged edge by cutting them off brought the edge delamination stress back to the undamaged value demonstrating that thermooxidative ageing begins at the surface. For the K3B laminate, no edge delamination was observed before lamination failure reflecting the higher toughness of this material and hence the better resistance to thermooxidative ageing. Little difference was identified whether the holes were drilled before or after ageing. While there would be some damage to

the matrix within the holes after ageing, the failure is still dominated by the local stress concentration on the 0° fibers at the hole.

### 3.32.5 Ageing in the Oil and Gas Industry

FRPs are key candidate materials for replacing carbon steel in the Oil and Gas Industry because of their good corrosion resistance and light weight. However, this industry is very risk averse and the uptake of these materials has been slow and is directly related to the operational risks for that component. The shortage of long-term performance data of FRPs in oil and gas applications does not aid their uptake. However, the potential improvements in component and system performance using FRPs will ultimately reduce capital and maintenance requirements, and this fact has enabled some usage of composites in the industry.<sup>24,25</sup>

The environments in the oil and gas industry can be very harsh. The fluids with which FRPs might come into contact include those illustrated in **Figure 2**, along with some of the potential ageing effects. The composition of crude oil varies around

the world from well to well. It mainly comprises aliphatic alkanes (hydrocarbons) such as hexane, octane, decane, etc. Aromatic hydrocarbons may also be present and these are known to swell epoxy matrices. The presence of corrosive media such as hydrogen sulfide or even carbon dioxide in water (carbonic acid) can chemically attack the entire composite, especially if a GRP is under load promoting environmental stress cracking/corrosion (ESC). In addition, most oil and gas operations are conducted at high temperatures (up to 200 °C) and at high pressures, helping to accelerate ageing of the material.

The notable uses of FRPs in this industry are in pipeworks, gratings, and blast and fire protection. Apart from hundreds of kilometers of GRP pipe used for transporting hydrocarbon and water lines in the Middle East, FRPs are also being increasingly used to line steel pipes where the FRP provides corrosion protection for the pipe bore by acting as a barrier to the passage of transported fluids. The composite-lined pipe solution is in direct competition with conventional corrosion-resistant alloy (CRA) systems for downhole and flowline/pipeline applications. Statoil Hydro pioneered the use of downhole tubing with composite materials in the North Sea. A Duoline 20 liner was examined after five years of

**Figure 2** Possible fluids used in the oil and gas industry and their effects on polymers.

service at up to 110°C and was found to be in excellent condition.<sup>26</sup> The technology has generally been confined to water injection service. A consortium project has been run by Oil States Industries UK to help understand the chemical compatibility of various types of FRP exposed to different oil field fluids, with the aim of obtaining 20-year life.<sup>27</sup> These liners see a variety of hostile media including hydrocarbons at temperatures up to 160°C, and short exposures to methanol, HCl/HF, and other fluids for cleaning operations. As part of the materials screening tests conducted at MERL, Hitchin, UK, single-point data was generated for specific conditions such as several days at 160°C in hydrocarbon and brine mix, 8 h of HCL exposure, etc. Several postexposure tests were conducted to ascertain surface degradation, weight change and mechanical property change of the liners. A picture of a glass-epoxy liner exposed to HCl for 8 h shows complete degradation (Figure 3).

GRP piping onshore is primarily filament-wound glass-epoxy and it has been successfully installed in 100 km runs in the Middle East for transport of hydrocarbons and other fluids. One of the shortcomings for these pipes is that the corrosion science of metals is much more developed and understood than the ageing and degradation of these materials. International standards exist for the design and installation of such pipework where short-term tests are used to account for such degradation and sufficient safety factors employed. DNV-OS-C501 standard discusses the various effects on mechanical properties under the influence of temperature, moisture and chemicals, and suggests that "... the degradation rates shall be obtained for the actual materials in question..." but gives no method for quantifying these effects in the long term. The ISO 14692 Part 2 Annex

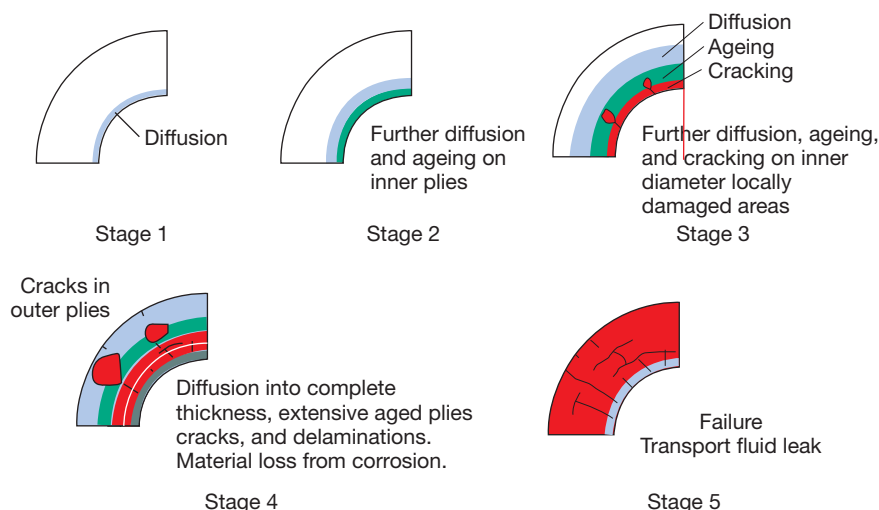

D provides information on defining partial factors A1/A2 to account for temperature and chemical resistance, respectively. These factors are used to give knockdowns on properties that were measured at standard temperatures. While values for determining A1 are well established, A2 can be generated for water but is less well identified for other chemicals. The standard makes recommendations of other standards (such as ASTM C 581) that can be used for deriving these factors for other chemicals, although these standards were not specifically written for determining A2 (see Section 3.32.6). While these approaches have allowed GRP piping to be specified, it is generally accepted that an improved approach of quantifying such degradation is needed.

Ageing from contact of the transport fluid in these GRP pipes occurs from the surface inwards and requires time to penetrate into the material's centre, as discussed above. The ageing or degradation of an FRP pipe has many stages and it is up to the user to determine at which phase failure is said to have occurred, Figure 4. Almost immediately at Stage 1, the fluid will diffuse into the polymer causing immediate physical changes. This is a complex phenomenon for an FRP material in contact with mixed fluids and is discussed further below. In Stage 2, the fluids would have diffused further into the FRP and the inner surface might have begun to chemically age. In Stage 3, the ageing is such that it has caused mechanical damage on the inner surface. Fluid diffusion and chemical ageing continue in Stage 3, but with the presence of cracks the fluid can now penetrate quicker. In Stage 4 diffusion, chemical ageing and mechanical damage has continued, but now the mechanical damage on the inner surface is sufficient for material to be removed. Stage 4 also shows cracks

**Figure 3** Section of glass-epoxy liner submitted to an HCl exposure. Courtesy of MERL.

**Figure 4** A schematic of GRP degradation when transporting a hostile fluid.

on the outside of the pipe from other damages such as erosion or UV degradation. Stage 5 shows complete damage through the pipe wall and subsequent leaking.

In most pipe designs, 'failure' should be considered as somewhere between Stages 1 and 3 and the influence on strength of the system evaluated to allow for sufficient safety factors (e.g., A2) to be applied.

In order to predict the life of an FRP laminate the following information needs to be known:

- The aged condition of the material and the profile through the thickness. This can be determined by knowing the rate of ageing (physical and chemical) for a given set of conditions (fluid type, temperature profile, time, etc.).
- The key material properties at a given amount of ageing. This depends on what is classed as the residual life of the pipe (see next bullet). The mechanical properties that are used to determine this residual life are those that have to be measured.
- The residual life of the structure with given damage and degradation profile; this is dependent on what is considered as failure for example, leak, global change in stiffness, % loss of material, inner cracking.

The technology for generating the information above does not exist at the time of publication.

The advantages of FRP gratings used offshore are obvious in the improved resistance to corrosion in a sea water environment and their durability and light weight, compare to metallic options, [Figure 5](#). The products are generally pultruded glass reinforced,

**Figure 5** A glass-phenolic grating on the Mars Platform in the Gulf of Mexico, Courtesy of Strongwell.

offering a cost-effective manufacturing method. The use of phenolic resins allows the parts to meet fire-resistance requirements offshore. An important driver for GRP gratings has been the ease of installation compared to steel. The ageing of these materials follows the same aspects as marine composites discussed in [Section 3.32.7](#) and includes hydrolysis and UV ageing. The fire resistance of these phenolic gratings is also a key reason behind their selection, but fire properties goes beyond the scope of this chapter.

Composites are also being increasingly used to protect subsea structures such as wellheads, and flowlines, protecting them from impact events such as dropped objects and commercial fishing operations. This is an accepted area of use where the perceived risks of adoption are outweighed by the benefits in performance and corrosion resistance. Another example of the use of composites in hostile

**Figure 6** Composite fire-blast protection enclosure. Reproduced with permission from Solvent Composite Systems Ltd.

environments is a ProTek(tm) Jet Fire and Blast protection enclosure manufactured from composite panels by Solent Composite Systems Ltd., **Figure 6**. This enclosure was installed at the LNG plant in the Arctic town of Hammerfest in northern Norway to protect emergency shutdown equipment. The composite structure resists an explosion pressure equivalent to 7 tonnes per square meter and protects against 90 min exposure to the erosive and heating effects of a hydrocarbon jet fire with a flame temperature of 1150°C resulting from a high pressure gas leak. During this period the equipment temperature does not exceed 65°C. The ageing aspects of long-term water exposure, biofouling, and hydrolysis are covered in **Section 3.32.7**.

### 3.32.6 Ageing in the Chemical Processing Industry

In the chemical processing industry (CPI), the environments for equipment such as reactor vessels, storage tanks, scrubbing towers, stacks, piping, valves, etc. may be extremely harsh (**Figure 7**). In many instances, corrosion-resistant alloys including highly alloyed stainless steel, titanium, and nickel-based alloys have

**Figure 7** FRP scrubbing tower. Courtesy of Dow Chemicals.

to be used and even these can corrode in these environments. One solution adopted in this industry is the use of FRPs in manufacturing this equipment.

FRP materials are used to a large extent in plants which manufacture chlorine, chlorate and concentrated acids (e.g., sulfuric, hydrochloric, hydrofluoric, nitric) as well as metal chloride solutions (e.g., NaCl, FeCl<sub>3</sub>, AlCl<sub>3</sub>, MgCl<sub>2</sub>, NiCl<sub>2</sub>).<sup>28</sup> FRPs are now also used in desulfurization plants (flue-gas ducting, scrubbers, etc.) which also have applications in oil and gas production. In many instances, a thermoplastic liner is used in the metallic and FRP pipes to act as a corrosion or permeation barrier, or both. The thermoplastic lining may be PA11, PVC, or PP; or for more aggressive service, PVDF. Because of the environmentally hostile nature of some of the chemicals being transported or stored, failure is unacceptable. However, failures do occur (**Figure 8**).<sup>29</sup> These failures may not only be very costly, but also present a health and safety risk to the workers at the plant, local residents and environment. The consequences and liability of equipment failure, even minor leaks, are becoming increasingly severe and have resulted in a very strict regulatory climate. Although FRP is often used to solve problems of corrosion on various metallic materials, these materials can still be affected by these fluids.<sup>30</sup>

The types of resins and fibers depend very much on the application being considered. Thermosetting

**Figure 8** Failure in alkaline aqueous solution at 70 °C. Courtesy of G. Bergman.

resins are suitable for large moldings and for filament wound pipes. The most important resin systems used for corrosion protection in the CPI include polyesters, epoxies, bismaleimides, phenolics, and vinyl esters.<sup>28,31</sup> Epoxies have certain advantages, in that they have lower cure shrinkage, adhere better to steel substrates, and offer better chemical resistance than polyesters towards hot alkalis. Vinyl esters are favored because they offer a compromise between epoxies and polyesters, offering good corrosion resistance with moderate relative cost. E-glass fiber is used as the reinforcement for the main structural part with a more chemical resistant fiber such as ECR-glass used in the layer in contact with the corrosive fluid. A protective resin-rich layer is often used on the surface adjacent to the acid.

Prediction methods for FRPs in the CPI must account for chemical ageing and include diffusion, hydrolysis and ultimately cracking, blisters and other damage. Eventually, this degradation may continue and lead to actual material loss from the inside of the vessels (Figure 9).<sup>32</sup>

Degradation in FRP composites may be defined as one of any of the following in the exposed surface:

• cracks	• loss of fiber	• etching
• pitting	• softening	• delamination
• thickness change	• blistering	• discoloration
• charring	• leaching	• fiber blossomin
• resin loss		

**Figure 9** Uniform corrosion in an FRP pipe after 14 years of service. The white line shows the original thickness. Courtesy of G. Bergman.

The published work related to chemical resistance of FRP materials in different environments has focused on immersion testing, rather than the more realistic single-sided exposure. Much of the published data quote only single-point data, for example, “The mass of material X increases by 10% in methanol after 10 days at 60 °C.” This information may be misleading because the overall trend may involve a mixture of competing mechanisms as discussed in previous sections. For hybrid materials (e.g., the use of a corrosion-resistant veil), the prediction method must account for the time for the ageing to reach each layer.

Further, FRPs may be subject to step changes in property changes leading to failure such as resin embrittlement. This failure is often termed environmental stress cracking (ESC) and also applies to the glass fibers when undergoing strains in excess of 2% and exposed to even dilute acids.<sup>33</sup> In any long-term evaluation, it is necessary to use diagnostic equipment to ensure that the cause for the change in properties of the FRP is understood.

Estimates of remaining life of FRP equipment in the CPI often rely on periodic visual inspection, intuition, and experience of the inspector. The inspector searches out defects such as blistering, delamination, or signs of leaking. Often a bright light is shone on the opposite side of the laminate to help reveal flaws. The inspector often also checks the condition of the laminate surface with a Barcol indentation tester. Drastic reduction in Barcol readings since the previous inspection indicates degradation. On the basis of these findings, the inspector will judge whether the equipment is still safe to operate and when the next inspection should occur.<sup>30</sup>

### 3.32.6.1 ASTM Standard for Long-Term Chemical Resistance

Materials are generally approved for long-term usage in the CPI using ASTM C 581 *Standard Practice for Determining Chemical Resistance of Thermosetting Resins Used in Glass-Fiber-Reinforced Structures Intended for Liquid Service*. This standard requires immersion of a material in a fluid at a single temperature. Various properties (Barcol hardness, flexural modulus and strength, and  $T_g$ ) are determined at intervals normally within one year. If the properties do not decrease by a certain amount, the material may be approved for long-term usage. However, this method does not offer an approach to allow an extrapolation to longer-term usage at varied of temperatures and is therefore little more than a screening test.

To demonstrate the use of ASTM C 581, an FRP laminate that may be used for the linings of tanks and vessels used to store acids was tested.<sup>30</sup> Plaques of materials were immersed in concentrated HCl or  $H_2SO_4$  for 12 months. Periodically, Barcol hardness, mass change, and flexural properties were measured on specimens cut from these plaques. The mass change is shown in Figure 10, illustrating that the material shows weight loss early in the exposures and the rate of weight loss begins to reduce as the test progresses. The change in Barcol hardness, shown in Figure 11, shows that there is an initial increase in both exposures, indicating that some form of local hardening has occurred. After 6 months' exposure, the hardness begins to decrease, leading to 10–15% from the starting values after 12 months. This indicates that there is more than one ageing mechanism

occurring and the resulting change in properties cannot be taken from only the end data point.

### 3.32.6.2 The Arrhenius Relationship

Using the different test parameters used in ASTM C 581 in the previous section, the feasibility of using an Arrhenius relationship was presented elsewhere.<sup>30</sup> Key to this approach being successful is that the elevated temperature exposures do not cause a change in the ageing mechanisms observed at lower temperatures.

A Derakane 411 vinyl ester resin was tested with two plies of 45g E-Glass chopped-strand mat, with a 0.25-mm C-glass veil. The materials were exposed to 37% HCl at temperatures of 40, 60, and 80 °C. Before and after the exposures, thickness and weight in air and water were measured to determine any changes. Following the ageing and the weighing, suitable specimens were cut from the plaques. Three point-bend tests were conducted and showed that the modulus initially increased before decreasing, whereas at the higher temperatures, the modulus and strength continually decreased, showing a change in mechanism at the different temperatures. The work demonstrated that there is an overall trend from test to test of a property change with exposure time, the rate of which increases with time. It is this general concept that lays foundation for developing accelerated ageing approaches using the Arrhenius equation if a single mechanism is present. The 5 and 10% change of flexural strength were plotted against the reciprocal of the absolute exposure temperature and a straight line fitted. The shorter-term,

Figure 10 Mass change of an FRP in concentrated acid.

Figure 11 % Change in Barcol hardness of an FRP in concentrated acid.

higher-temperature exposure tests were able to predict the properties at lower-temperature exposures. The energy of activation for this change is in the region of  $80 \text{ kJ mol}^{-1}$ , which is indicative of chemical ageing. However, an Arrhenius curve cannot be drawn for the modulus because of the initial increase in modulus in the early exposure times, this invalidating this method unless the different mechanisms are separated.

### 3.32.6.3 Using a Semiempirical Corrosion Approach

Another approach to the long-term ageing of FRPs is to relate the effects of ageing to those of corrosion in metals, because on the macrolevel the results are very similar. Many types of corrosion found in metals can also be found in FRP, such as uniform corrosion (material loss), localized corrosion (pitting), selective corrosion, stress corrosion, corrosion fatigue, erosion corrosion, and layer corrosion (delamination). CFRPs are conductive and galvanic corrosion effects may arise when being coupled to a metal component.

On the basis of the results of corrosion analyses of samples taken from FRP equipment used for different chlorine dioxide environments in various pulp mill applications over a period of 20 years, a semiempirical relationship for uniform corrosion behavior of FRP in chlorine dioxide environments has been established,<sup>32</sup>

$$\Phi = Bt^\alpha cA \exp\left(\frac{-E_a}{RT}\right) \quad [4]$$

where  $\Phi$  is the depth of corrosion (mm),  $B$  is a special factor in case of protective deposits on the surface (usually  $B = 0$  or  $1$ ),  $t$  is the time in service (years),  $\alpha$  is a factor which depends on the thickness and degree of degradation of the corroded surface layer (usually  $\alpha$  is between  $0.5$  and  $1$ ),  $c$  is the concentration of chlorine dioxide ( $\text{g l}^{-1}$ ),  $A$  is a material constant which depends on the type of resin, the degree of curing, and the laminate structure,  $E_a$  is the activation energy of the rate-controlling step of the corrosion process ( $\text{kJ mol}^{-1}$ ),  $R$  is the general gas constant ( $8.3 \text{ J mol}^{-1} \text{ K}$ ),  $T$  is the temperature (K).

This expression is not proven for other applications and environments, although the premise should hold.

### 3.32.7 Ageing in the Marine Industry

One of the more established uses of FRPs with long and chopped fiber resins in marine vessels from small

dinghies to racing yachts. A review of marine composites is given elsewhere.<sup>34,35</sup> The FRP materials are mainly E-glass reinforced polyester and epoxy, but with the high-performance vessels carbon fiber composites and a range of sandwich materials are now used. Almost always, a protective outer coating or gelcoat is used to help prevent diffusion and to give a better appearance. There is much experience on the ageing of these materials in this environment. However, similar to the studies in other industries, research studies on ageing for this industry have focused on short-term ageing tests under severe conditions that may have little relationship with in-service use.

Leisure craft or pleasure boats, defined as vessels built for recreational purposes, were one of the first applications of FRPs. The average lifetime of a FRP pleasure boat is 30 years, demonstrating the anticipated long use life of these materials. For commercial vessels including fast ferries, lifeboats, fishing boats, and some military vessels have been made from a conventional GRP material since the 1960s. Some vessels such as mine countermeasure vessels are in excess of 40 m length and the nonmagnetic and conducting properties of the GRP add another advantage to the use of these materials. The low weight of FRP materials make them attractive for submarine use in internal and external structures such as sonar domes.

Woven or chopped glass strand mats in a polyester resin is the typical FRP use in marine applications and much work on ageing of these materials in a sea water environment has been conducted.<sup>36</sup> Higher-end materials, including stitched multiaxial cloth, carbon epoxy are used for the higher end applications where ageing may be less of a concern such as in racing yachts. The document also provides a database of material properties to be used if test data are not available. Typical hull laminate thicknesses vary from 5 mm for pleasure craft up to 150 mm for hulls that must survive underwater explosions. The difference in thickness has an affect on the time to reach equilibrium and hence begin hydrolytic ageing. Manufacturing techniques have been developed over the past 10 years to utilize resin infusion to draw the resin through the dry fibers. This has resulted in the ability to have a higher fiber to resin volume fraction giving thinner laminates with the same strength as the previously used wet lay-up manufacturing methods with lower volume fractions. Sandwich panels comprising a core (foam or balsa-wood) surrounded by thin layers or skins of FRP are a preferred manufacturing method for large hulls. However, the thin skins, their bonding to the core

and degradation of the core material present further concerns for ageing. As mentioned above, a gelcoat is almost always used and this serves to protect the laminate.

There are a number of different damage modes for marine composites and the gelcoats, including osmosis, blisters, pinholes, wrinkling, debonding/delamination, crazing, etc., can all be considered a form of ageing. Blisters are a particular ageing damage mode in marine environments, where the osmotic pressure is developed between the gelcoat and the FRP. This is built up from products such as glycols leached from the base FRP and can cause local delamination or blisters and is particularly apparent with a gelcoat that is more permeable than the base laminate. The temperature and the composition of the seawater, which varies around the world, are important aspects in considering ageing of marine FRPs as well as the loading from wave load, slamming load, hydrostatic pressure, etc. Antifoul treatments are used on many boats to prevent biofouling or marine growth. These are applied to the gelcoat and may in themselves age the coating.

Conventional marine ageing of a marine FRP follows the same degradation mechanisms as discussed in [Section 3.32.2.2](#). This is physical ageing causing plasticization and swelling (potentially leading to interfacial debonding and delaminations) and chemical ageing such as hydrolysis of the matrix and, in saltwater environments, the fiber and the fiber–matrix interface. Many of the ageing studies are conducted at higher temperatures to reduce the ageing times. A number of case studies are presented in Searle and Summerscales,<sup>36</sup> where an attempt to better understand the changes due to ageing of properties that can be used for design were studied. In one study, weight change was measured along with shear strength and modulus for three GRPs (polyester, vinyl ester, and epoxy, all with the same glass reinforcement). The work demonstrated that the resin and fiber interface within an FRP absorbs water, not just the resin. In the same work, FRP materials were exposed to an accelerated exposure (elevated temperature), and the same panels were exposed to the sea for up to a year. The results suggest that without due attention to the various ageing conditions, the accelerated test will overpredict changes in properties.

For realistic accelerated ageing of marine FRPs, several aspects need to be considered. Virtually, all laminates, as stated above, will have a gelcoat. While not an impermeable layer, it is a resin-rich layer and needs to be considered in ageing analysis. The work in Searle and Summerscales<sup>36</sup> demonstrated that the

composition of the water can greatly affect the ageing of the FRP. Seawater will diffuse into polymers slower than distilled water, and ageing exposure using distilled water may be overly conservative. In addition, during ageing, products may leach out of the FRP into the water. These products will themselves change the composition of the water more significantly if small vessels and hence small volumes of water are used. As for other applications, the use of temperature as an ageing accelerator must be used with caution. The increase in temperature can serve to promote further cross-linking in partially cured polyesters and use of ageing temperatures near or above the  $T_g$  can cause degradation mechanisms that will never occur at lower temperatures. For true comparisons for sea environments, it is the inclusion of biofilms that will develop, followed by biofouling, resulting in a complete covering. This needs to be considered when conducting weight-gain/loss measurements and the influence of the living matter on the properties of the composites needs to be better understood.

### 3.32.8 Concluding Remarks

This chapter has described some of the more common forms of ageing of FRPs. Ageing is a summation word for degradation and can include physical changes of the matrix such as swelling or irreversible chemical changes such as hydrolysis or oxidation. The extent of the degradation is very much dependent on the exposure the FRP material will experience including the fluid in contact, time, pressure, temperature, load applied, if any, etc. Some attempts have been to develop predictive modeling capability for the long-term durability assessment of FRP components, but this still remains an area for further research. As the use of FRP materials increases and the demands for extended performance grow, so does the need and importance to develop predictive capability for assigning the fitness for the purpose of an FRP structure at any time during its service.

## Glossary

### Damping Basic property of an

elastomer to dampen, absorb or reduce vibrations. High damping elastomers are those having high glass-transition temperature ( $T_g$ ), which are widely used to isolate vibrations.

**Glass-transition temperature ( $T_g$ )** It denotes the temperature below which the elastomer becomes glassy and brittle, above which it is soft and rubbery.  $T_g$  reflects molecular mobility and hence the internal viscosity of the elastomer. High  $T_g$  indicates low molecular mobility or high internal viscosity and vice versa.

**Heat build-up** The amount of heat accumulated in the elastomer when subject to cyclic deformation. It is closely related to hysteresis.

**Hysteresis** It is a term to denote energy dissipated as heat when the elastomer is subject to cyclic stresses or in a single stress-strain cycle. The area bounded by the extension and retraction curve gives a quantitative measure of hysteresis.

**Raw rubber** Fresh rubber or an elastomer as received from the supplier.

**Scorch** It is a rubber technology term to denote the occurrence of a premature crosslink, which is an undesirable feature during the shaping process.

**Vulcanize or vulcanized elastomer** Indicates rubber or elastomer that has been vulcanized or cured, and thus, contains network structure or chemical crosslinks.

**CM** Cement metal failure

**CP** Cement primer failure

**CR** Polychloroprene rubber

**CSM** Chlorosulfonated polyethylene rubber

**DCP** Dicumyl peroxide

<b>χ</b>	Rubber-solvent interaction parameter

### 3.33.1 Introduction

Natural rubber and elastomers belong to the same group of materials known as high molecular weight polymers. According to the International Organization for Standardization (ISO) rubber vocabulary,<sup>1</sup> an elastomer is a macromolecular material which returns rapidly to approximately its initial dimensions and shape after substantial deformation by a weak stress

and release of the stress. However, an elastomer has always been recognized as a synthetic elastic polymer.<sup>1</sup> A polymer is a high molecular weight material having many units of small molecules chemically joined or linked by normal covalent bonds to form long chain molecules. These flexible and soft materials find wide uses in many engineering applications, such as natural rubber (NR) bridge bearings, and earthquake and seismic bearings. Indeed NR has had a sound track record in many engineering applications for over 150 years.<sup>2</sup> Elastomers have some unique properties that metals do not have. These include

- high bulk modulus (2000–3000 MPa) relative to their Young's modulus (0.5–3.0 MPa),
- some inherent damping, and
- large strain deformation.

Rubbers having high bulk modulus hardly change their volume when deformed. In simple words, rubber is incompressible. Like incompressible liquids, it has a Poisson's ratio close to 0.5. If rubber is constrained, to prevent changes in shape, it becomes much stiffer, a feature that is used to full advantage in the design of compression springs. Elastomeric bridge bearings and seismic bearings are examples of products that rely on these properties.

The damping inherent in the elastomer is a very important property as it helps to prevent the amplitude of the vibration of the spring from becoming excessive if resonant frequencies are encountered. Elastomeric products such as vibration isolators and engine mounts rely on the inherent damping properties of the elastomer.

The elastomer undergoes large strain deformation (a few hundred percent) without failure by an applied stress below its breaking stress. This means that it can store much more energy per unit volume than steel. Elastomeric dock fender systems make use of its large stored energy capacity to absorb shocks, blows and the impact exerted by ships.

Some of the merits of elastomeric springs over metal springs are as follows<sup>2</sup>:

- no maintenance is required,
- the energy storage capacity is high,
- with correct design, the rubber spring can provide different stiffness in different directions, or nonlinear load–deflection characteristics,
- a certain amount of misalignment is tolerable as the rubber spring can accommodate this tolerance,
- easier to install,
- hysteresis inherited by the elastomer is able to dampen dangerous resonant vibrations.

Another important property of an elastomer is its strong resistance to inorganic acids, salts, and alkalis. In contrast, acids attack metals. For these reasons, the linings of chemical tanks and pipes, especially those containing caustic solutions, are made from elastomers. The function of the elastomer here is to protect the metal against attack by corrosive chemicals.

Every product has its own life span. The designed lifetime of a product depends on the environmental conditions and the nature of the application. It is very important to choose the materials correctly to meet the intended service conditions and the surrounding environment. The aging process is the determining factor that limits the life span of the product. The term aging is always associated with the degradation or corrosion process as applied to metals, which may take many forms. In metals, corrosion takes place in the form of rusting, which involves oxygen and moisture. In elastomers, the term degradation is preferred to corrosion and covers a wider scope than that of metals. Degradation takes place in the form of oxidation, ozone cracking, flex cracking, liquid absorption and heat aging. Degradation in elastomers is very complex as it involves oxygen, ozone, mechanical strain, heat, trace metals, etc. There are other agencies such as solvents, oils, fuels, hot air (steam) and water, which may degrade elastomers and affect the service life of elastomeric products. A specific section on the degradation of elastomers discusses all these issues again later.

### 3.33.2 Classifications of Rubber and Elastomers

#### 3.33.2.1 Classification in Terms of Origins

Natural rubber comes from trees known as *Hevea brasiliensis*, and shrubs called guayule. The pictures in Figure 1 show typical rubber trees grown in the hot tropical climate of Malaysia, and the fresh latex that exudes from the bark of the rubber tree, after tapping with a sharp tapping knife. The fresh latex that exudes from the tree known as field latex contains about 70% water. After removing this large amount of unwanted water, the latex is known as concentrated latex and has about 60% of rubber content. Centrifuging is the preferred method of concentrating field latex because of its efficiency and rapidness compared to creaming and evaporation methods. Apart from latex, natural rubbers are available commercially in standard bale form, weighing about 33.33 kg. These bales of NR are produced specifically to meet certain

**Figure 1** Pictures of (a) natural rubber trees (top), (b) NR latex exudes from natural rubber tree (middle), and (c) closer view of NR latex collected in a cup (bottom).

technical requirements such as minimum dirt content, viscosity consistency, ash content, etc.

All synthetic elastomers are produced by the polymerization process. The early production of synthetic elastomers such as styrene butadiene rubber (SBR), polychloroprene rubber (CR), and nitrile rubber (NBR) relied on emulsion polymerization. One of the main drawbacks of emulsion polymerization is the lack of uniformity of polymer molecules with respect to stereo regularity. This is due to the

different ways in which diene monomer molecules can react, and it applies to all free radical polymerization processes of diene monomers. However, there was a real breakthrough with the discovery of the Ziegler–Natta catalyst in 1954, which enabled the control of the microstructure of polyisoprene.<sup>3</sup> Synthetic polyisoprene is produced by the solution polymerization process using catalysts of the alkyl lithium types such as trialkyl aluminum/titanium tetrachloride mixtures.<sup>3</sup> The Al/Ti mole ratio is critical for achieving high cis content. Currently, there are about 27 types of rubbers or more commercially available in the market. The choice depends on the nature of application, service conditions and environment.

### 3.33.2.2 Classification in Terms of Purposes

Elastomers can be classified further either as general-purpose rubbers or as specialty rubbers. General-purpose rubbers are those elastomers that are widely used in the manufacture of tires, industrial rubber goods (IRG), and general rubber goods (GRG). Most of the general-purpose elastomers cannot meet high service temperature and high oil resistance specifications or the combinations of these two requirements. The most common general-purpose rubbers include NR, SBR, CR, NBR, ethylene–propylene–diene rubber (EPDM), and BR. In contrast, specialty rubbers are those elastomers that are tailor made to meet certain specific requirements, such as low temperature flexibility, high swelling resistance towards oil (hydrocarbon, fuel, gasoline, etc.) and very high service temperature or combinations of these requirements. Specialty rubbers include silicone rubber, fluoroleastomers, epichlorohydrin, chlorosulfonated rubber, etc. [Table 1](#) shows some of the rubbers which belong to these grades and their typical applications.

### 3.33.2.3 Classification in Accordance with International Organization for Standardization

Elastomers can also be classified according to the ISO 4632/1-1982(E)<sup>4</sup> which provides information about rubber as a material with specifications. They are classified and designated in terms of their performance to heat aging, swelling resistance towards oil and low temperature flexibility. This method of classification is very helpful as it facilitates the purchasers and suppliers to make the correct selection of suitable materials, and avoid wasting time and energy.

These designations are determined by a type based on resistance to heat aging, by a class based on resistance to swelling in oil, and by a group based on low temperature resistance.<sup>4</sup> These classification criteria are used to establish a characteristic material designation consisting of three capital letters, where

- the first letter signifies Type (heat resistance)
- the second letter signifies Class (oil resistance)
- the third letter signifies Group (low temperature resistance).

[Tables 2–4](#) show the heat aging temperature, limits of volume swell and brittleness temperature for establishing Type, Class and Group respectively.<sup>4</sup> Type is determined by the maximum temperature at which heat (air oven) aging for 70 h, in accordance with ISO 188, causes a change in tensile strength of not more than  $\pm 30\%$ , a change in elongation at break of not more than  $-50\%$ , and a change in hardness of not more than  $\pm 15$  International Rubber Hardness Degrees (IHRD). Class is based on the resistance of the material to swelling in American Society for Testing Materials (ASTM) Oil No. 3, when tested in accordance with ISO 1817. In the test, the immersion time shall be 70 h at a temperature determined in [Table 2](#). Group is based on the brittleness temperature of the material when measured in accordance with ISO/R 812.

Thus if an elastomer is designated as BCD, it means that it is classified as Type B, Class C and Group D. This implies that the elastomer resists temperatures up to  $100^{\circ}\text{C}$ , with volume swelling not exceeding 120% in oil No. 3 and is not brittle at  $-40^{\circ}\text{C}$ .

Most of the general purpose elastomers shown in [Table 1](#) have poor heat resistance except for ethylene propylene rubber (EPM) as shown in [Figure 2](#). EPM can withstand service temperature of about  $150^{\circ}\text{C}$  as it is categorized as Type D. General purpose elastomers also have poor swelling resistance towards hydrocarbon oil except nitrile rubber (NBR) which is classified as Class H with maximum volume swell of 30%. A majority of the specialty elastomers shown in [Table 1](#) have both excellent heat resistance and swelling resistance. From the chart shown in [Figure 2](#), silicone rubber having both methyl and vinyl substituent groups on the polymer chain (VMQ) has equivalent heat resistant (Type G) with silicone rubber having methyl, vinyl, and fluorine substituent groups on the polymer chain (FVMQ). However, they have different Class with respect to swelling resistance. VMQ belongs to Class E while FVMQ belongs to Class J. Clearly

**Table 1** General purpose rubbers and specialty rubbers

<i>General purpose rubbers</i>	<i>Typical applications</i>	<i>Specialty rubbers</i>	<i>Typical applications</i>
Natural rubber (NR)	Mainly for tires, industrial and general rubber goods, bridge and earthquake bearings, bridge expansion joints, etc.	Carboxylated nitrile rubber (XNBR)	Oil resistant hoses, boots, seals and gaskets and other automotive components with very good oxidation resistance
Synthetic polyisoprene (IR)	Tires, sports goods, earthquake rubber bearings, IRG.	Polysulphide rubber (PTR)	Used mainly where good resistance to solvents is required
Styrene butadiene rubber (SBR)	Passenger car tires, IRG, GRG	Polyurethane rubber (AU, EU)	Gaskets, seals, solid tires, and foams
Butyl rubber (IIR)	Tire tubes, tube liners, enclosures, air bags, and curing bladders	Silicone rubber (Si)	Able to withstand a very wide range of service temperatures from $-45$ to $200^{\circ}\text{C}$ . Various grades are available covering a very wide range of applications such as baby teats, catheters, medical applications, wire and cables, electronic components, etc.
Butadiene rubber (BR)	Tires, sports goods	Chlorosulfonated polyethylene rubber (CSM)	Electrical insulator in cable and wire industry, tank lining, colored-stable weather-resistance products, oil resistant hoses and gaskets
Ethylene-propylene-diene rubber (EPDM)	Gaskets, seals, automotive components, IRG, and GRG	Polyacrylic rubber (ACM)	Seals and gaskets for high temperature applications, $180-200^{\circ}\text{C}$
Polychloroprene rubber (CR)	Hoses, rubber bearings, expansion joints, belts, and conveyors	Fluorocarbon rubber (FPM)	Products which are resistant to chemicals, oils and solvents. Able to withstand high service temperatures exceeding $250^{\circ}\text{C}$ . Outstanding oxidation and ozone resistance. Flame resistant. Hoses, gaskets and seals for aircraft, jets, and rockets
Nitrile rubber (NBR)	Oil-resistant hoses, seals, O-rings, gaskets	Epichlorohydrin rubber (ECO)	Automotive industry – gasket, seals, hoses to withstand service temperatures above $130^{\circ}\text{C}$

**Table 2** Heat aging temperature for establishing Type<sup>4</sup>

**Figure 2** A chart showing type and class of elastomers. Adapted from Hashimoto, K.; Maeda, A.; Hosoya, K.; Todani, Y. *Rubb. Chem. Technol.* **1998**, 70(3), 449–519, with permission from American Chemical Society.

FVMQ is more resistant to swelling towards the solvent than VMQ grade, as the fluorine atom is highly polar. **Figure 3** shows the general chemical structure of silicone rubber with different substituent groups.

The main backbone chain is made of repeating  $-\text{Si}-\text{O}-$  groups while the methyl groups are attached at the side. Both  $\text{Si}-\text{O}$  and  $\text{Si}-\text{CH}_3$  bonds are thermally stable. This explains why VMQ and FVMQ grades have the same Type of heat resistance, as the main chain backbone is the same for both. The  $\text{Si}-\text{O}$  bond is partially ionic and it is relatively easy to be broken by concentrated acids and alkalis even at room temperature. Another important feature of the chemical structure of silicone rubber is the relatively large bond angle of  $\text{Si}-\text{O}$  (about  $140^\circ$ – $160^\circ$ ).<sup>7</sup> The intermolecular forces between silicone chains are very low probably because of the large distance between the adjacent chains, as silicone atoms are relatively large. Thus this facilitates ease of chain rotation which accounts for the lowest glass-transition temperature  $T_g$  ( $\sim -120^\circ\text{C}$ ) among the commercially available elastomers. The dimethyl rubbers swell more in aliphatic and aromatic hydrocarbons than in acetone and diesters. However, the swelling resistance towards hydrocarbon oil can be enhanced by the replacement of one methyl group on each silicon atom by a more polar group such as trifluoropropyl group ( $-\text{CH}_2\text{CH}_2\text{CF}_3$ ), that is, the FVMQ grade.

### 3.33.3 General Properties of Elastomers

All elastomers have some common properties such as being flexible, tough, relatively impermeable to both water and air, and elastic when vulcanized. One of the unique features of a vulcanized elastomer is its ability to exhibit high elasticity: the elastomer can be stretched to a few hundred percent and recover its original shape and dimensions almost instantaneously when the deforming force is released. For a material to exhibit high elasticity, it must fulfill the following conditions:

- flexible long chain molecules with relatively low molecular interaction forces,
- the long chain molecules must be cross linked (at least 2% cross linked network),
- rubbery above  $T_g$

The elasticity of an ordinary solid such as metal is associated with its internal energy. In contrast, the elasticity of rubber is entropy driven.

Elastomers are also well known for their good resistance to acids, alkali and chemical solutions. Elastomers have a proven record of accomplishment as the material used for tank lining or related chemical vessels. Beyond these common characteristics, each rubber has its own unique properties depending on the chemical structure as discussed briefly below.

#### 3.33.3.1 Structure–Property Relationship

The effects of chemical structure on some important physical and technological properties are summarized in **Table 5**.

##### 3.33.3.1.1 Mechanical strength

Tensile strength, tear strength, crack-growth resistance and fatigue life of the vulcanized elastomer depend on the chemical structure and its geometrical configurations. Elastomers having regular microstructure are able to crystallize, and those that have irregular microstructure are amorphous. **Figure 4** shows the chemical structure of general-purpose elastomers such

**Figure 3** Chemical structure of silicone rubber: MQ grade consists of methyl, PMQ grade consists of benzene rings and VMQ grade consists of vinyl.

**Table 5** Influence of chemical structure on physical and technological properties of elastomers

Basic structure	Technological significance
1. Nature of carbon-carbon backbone chain (i) Double bonds (ii) Single bonds	Unsaturated elastomers (having double bonds) are capable of being vulcanized with sulfur. Saturated elastomers (having single bonds) cannot be vulcanized with sulfur, but with peroxide. Unsaturated elastomers have poorer ozone cracking resistance and poorer oxidative resistance than saturated elastomers
2. Geometrical configurations	Regular microstructure would favor crystallization. Irregular microstructure leads to amorphous elastomers. The degree of crystallization affects mechanical strength
3. Polarity	Affects the degree of swelling resistance, rubber to metal bond strength, $T_g$ and electrical resistivity
4. Chain flexibility and glass transition temperature, $T_g$	Affects hysteresis and damping, and other related properties such as resilience, heat build-up, mechanical strengths, etc.
5. Molecular weight distribution	Broad molecular weight distribution provides easier processing than narrow molecular weight distribution

as natural rubber (NR), styrene butadiene rubber (SBR) and polychloroprene rubber (CR).

Natural rubber is 100% *cis*-1,4-polyisoprene indicating that it has regular microstructure, thus enabling it to crystallize. NR will crystallize at low temperatures. Crystallization has its own kinetic; in the case of NR the maximum rate of crystallization occurs at  $-26^\circ\text{C}$ .<sup>2,6</sup> When the rubber crystallizes, it hardens progressively and eventually loses its flexibility and rubber-like elasticity. The maximum amount of crystalline region is about 33% in the case of NR. However, if a tensile strain (more than 200%) is applied to NR it crystallizes almost instantaneously even at high temperatures. This phenomenon is known as strain-induced crystallization. Since crystallization is a reversible process, the crystals are completely melted once the applied strain is removed.

Low temperature crystallization brings few disadvantages to NR, particularly when it involves mixing. When NR crystallizes, it becomes very stiff and may cause damage to the mills. To overcome this problem, the common practice is to place the crystallized NR in a hot room (oven) to melt the crystals so that the rubber regains its flexibility. Any unmelted crystals

present during the mixing process would interfere with the incorporation and dispersion of the compounding ingredients. In contrast, strain-induced crystallization offers a big advantage in that it helps to enhance the mechanical strength of the rubber. For example, an unfilled or gum NR vulcanizate gives higher tensile strength (23–27 MPa) than unfilled SBR gum vulcanizate (2–3 MPa). Unfilled (gum) vulcanizate refers to a vulcanized rubber containing no filler apart from the compounding ingredients necessary for vulcanization. The crystals that are formed during straining act like a reinforcing filler to enhance the tensile strength. Thus for a noncrystallizing elastomer, it is necessary to incorporate a reinforcing filler into the rubber to enhance its strength.

In addition to the reinforcing filler, the types of chemical crosslink such as polysulfidic (C–S<sub>x</sub>–C), monosulfidic (C–S–C), or carbon-carbon (C–C) also affect the strength of the vulcanized elastomer.<sup>8</sup> Polysulfidic crosslinks are weak and labile with lower bond energy than monosulfidic and carbon-carbon links. Polysulfidic crosslinks enhance mechanical strengths such as tensile and tear strengths because these weak and labile crosslinks relieve stresses by ‘yielding.’<sup>8</sup>

**Figure 4** Chemical structure of general-purpose elastomers.

Besides NR, polychloroprene rubber (CR) can also crystallize. Indeed CR crystallizes more readily than NR does because trans 1,4 configuration allows better molecular packing than cis 1,4 configuration.

### 3.33.3.1.2 Oxidation and ozone resistance

All unsaturated elastomers are susceptible to attack by oxygen and ozone which ultimately leads to chain scission followed by progressive loss in the physical properties. This aspect of oxidation will be discussed further in a later section. Almost all specialty elastomers have saturated bonds on the main backbone as well as high bond dissociation energy. Thus, specialty elastomers are highly resistance to heat, oxidation and ozone cracking.

### 3.33.3.1.3 Swelling resistance

The swelling resistance of rubber towards hydrocarbon oil depends on the extent of the polarity of the elastomer. The more the polar groups attached to the rubber molecules the higher is the polarity, and

the better is the swelling resistance towards hydrocarbon oil. The solubility parameter of elastomers and liquids determines the extent of compatibility and swelling resistance. The closer the solubility parameters between the elastomer and the liquid, the better is their compatibility. Indeed, the greater the thermodynamic compatibility between liquid and elastomer, the greater the absorption of liquid occurring when both have similar solubility parameters. The solubility parameter  $\delta$  is related to a parameter to measure the specific interaction between molecules known as cohesive energy density (CED) by the following mathematical relationship.

$$\delta = (\text{CED})^{1/2} \quad [1]$$

$$\text{CED} = (\Delta H - RT)/(M/\rho) \quad [2]$$

where  $\Delta H$  is the latent heat of vaporization,  $T$  is the absolute temperature,  $M$  is the molecular weight of the polymer,  $\rho$  is the density of the polymer, and  $R$  is the molar gas constant. For example, natural rubber has a solubility parameter value of 16.7 and NBR has

a solubility parameter between 21.0 and 22.0 MPa<sup>1/2</sup>. Most of the petroleum oils have a solubility parameter of 16.3 MPa<sup>1/2</sup>. Thus NR will swell markedly in petroleum oil because their solubility parameters are similar. In contrast, NBR has a solubility parameter very much higher than that of petroleum oil, so the two are not compatible. For this reason, polar NBR shows higher swelling resistance than nonpolar NR towards petroleum oil. Elastomers with higher polarity such as polyurethane rubber (AU) show even higher swelling resistance to nonpolar solvents than nonpolar elastomers. Based on the solubility parameter, polar rubbers swell more in polar solvents. Nonpolar rubbers are resistant to swelling in polar solvents.

#### 3.33.3.1.4 Glass-transition temperature $T_g$

The glass-transition temperature ( $T_g$ ) is the temperature at which molecular mobility begins to take place, below which molecular mobility is frozen and the elastomer becomes rigid and glassy. The  $T_g$  of the elastomer depends on the chemical structure of the elastomer. The presence of a polar atom, side groups, length of side chains, and crosslink reduces molecular mobility which would increase  $T_g$  of the elastomer. The glass-transition temperature affects a number of important technological properties such as strength, damping, low temperature flexibility, rolling resistance, wet grip, etc. High  $T_g$  elastomers are preferred to low  $T_g$  elastomers for applications where high mechanical strength, high damping, and excellent wet traction are required. For applications where excellent low temperature flexibility, low heat

generation, high resilience and low rolling resistance are required, low  $T_g$  elastomers are preferred to high  $T_g$  elastomers.

**Table 6** summarizes the respective  $T_g$ , ozone cracking resistance, chemical resistance and heat aging resistance of some of the important commercial elastomers.

### 3.33.4 Rubber Technology and Compounding

#### 3.33.4.1 Mastication and Mixing

Rubbers find very limited applications in their raw form. In their raw form, rubbers may be suitably used as binders and adhesives because of their inherent tack. To become useful products, they have to undergo various processes from mastication, mixing, shaping or fabrication prior to molding, as shown by the schematic flow chart in **Figure 5**.

#### 3.33.4.2 Rubber Compounding

Rubber compounding is the term used to denote the art and science of selecting and combining elastomers and additives to obtain an intimate mixture that will develop the necessary physical and chemical properties for a finished product. In compounding, one must cope with literally hundreds of variables in materials and equipment. There are three main areas of concern in rubber compounding, namely, (i) to secure certain properties in the finished product to

**Table 6** Some important technological properties of some important commercial elastomers

Elastomer	$T_g$ (°C)	O <sub>3</sub> resistance	Swelling resistance (%) <sup>a</sup>	Heat resistant up to (°C) <sup>b</sup>
NR	-72	L	200 (120 °C)	100

**Figure 5** Schematic flow process chart.

satisfy service performance; (ii) to be able to meet processing characteristics for efficient utilization of available equipment, and (iii) to meet conditions (i) and (ii) at the lowest possible cost. In other words, the most important criteria in compounding are to secure an acceptable balance among demands arising from the three concerned areas.

Theoretically, a rubber compound may consist of an elastomer and a cross linking agent. However, in practice, a rubber compound may contain 5 ingredients or even more than 10 ingredients, depending on the intended products, types of application and their service conditions. Each ingredient has a specific role and function(s). Each has an impact on properties, processability, and price. The real challenge is to develop a high quality rubber product at the lowest cost possible. The materials utilized by the rubber compounder can be classified into nine major categories, which are defined as follows:

- **Elastomers:** The basic component of all rubber compounds may be in the form of rubber alone, or master batches of rubber–oil, rubber–carbon black, or rubber–oil–carbon black.
- **Vulcanization agents:** These materials are necessary for vulcanization processes where chemical crosslinks are introduced into the rubber matrix to form a three-dimensional network. Crosslinks inhibit permanent flow under deformation or heat and prevent dissolution in solvents. Strength, stiffness and resilience increase upon cross linking, and set, stress-relaxation and creep decrease.
- **Accelerators:** In combination with vulcanizing agents, these materials reduce the vulcanization time (cure time) by increasing the rate of vulcanization. In most

cases, the physical properties of the products are also improved.

- **Activators:** These ingredients form chemical complexes with accelerators, and thus aid in obtaining the maximum benefit from an acceleration system by increasing vulcanization rates and improving the final properties of the products.
- **Age-resistors:** Antioxidants, antiozonants, and other materials are used to slow down ageing processes in the vulcanizates.
- **Fillers:** These materials are used to reinforce or modify physical properties, impart certain processing properties, and reduce cost.
- **Processing additives:** Formerly known as processing aids, the new term currently used is processing additives. These are materials used to modify rubber during the mixing or processing steps, or to aid in a specific manner during extrusion, calendering, or molding operations.
- **Softeners:** They are materials that can be added to rubber either to aid mixing, produce tack, or extend a portion of the rubber hydrocarbon (e.g., oil extended).
- **Miscellaneous ingredients:** These materials can be used for specific purposes but are not normally required in the majority of rubber compounds. They include retarders, colors, blowing agents, abrasives, dusting agents, odorants, etc.

### 3.33.4.3 Vulcanization

Vulcanization is a process of cross-linking rubber molecules chemically with organic/inorganic substance through the action of heat and pressure. The

rubber which is cross linked chemically is known as vulcanizate. The introduction of crosslinks into the rubber matrix may be comparatively few in number but are sufficient to prevent unrestricted flow of the whole molecules past neighboring ones. The low concentration of crosslinks implies that the vast majority of the segments making up the long chain molecules are free to move by virtue of kinetic energy. An unvulcanized rubber dissolves completely in its solvent. In contrast, a vulcanized rubber only swells. The chemical crosslinks prevent complete dissolution. A vulcanized rubber in this sense is a solid and will retain its shape and dimensions.

Vulcanization is a very important process in the rubber industry and conducted at relatively high temperatures (140–200 °C). For latex dipped goods, vulcanization is conducted at relatively low temperatures (60–120 °C) and requires no pressure as the latex is in fluid form and flows to take the final shape of the former and mold.

One of the most important chemicals in vulcanization is the cross linking agent. Elemental sulfur is the most widely used cross linking agent in the rubber industry because it is very cheap, abundant and easily available. Besides, sulfur is very easy to mix and readily soluble in the rubber. By varying the amount of sulfur to the accelerator ratio one can get different types of crosslink in the rubber matrix. Table 7 summarizes the types of sulfur vulcanization system,<sup>10</sup> nature of crosslinks produced and their influence on technological properties. Thus sulfur vulcanization provides flexibility as one can control the type of crosslink intended for specific use or applications. The most basic requirement for sulfur vulcanization is the availability of double bonds on the rubber hydrocarbon. The nonsulfur cross-linking agents include organic peroxides, quinines and their oximes and imines, metallic oxides and high energy radiation. The detailed mechanisms of vulcanization with these vulcanizing agents are discussed by Elliot and Tidd.<sup>10</sup>

There is another type of sulfur vulcanization system known as soluble efficient vulcanization (EV)<sup>10</sup> intended for engineering products that require consistent stiffness, low creep, low stress-relaxation and low set. This vulcanization system employs certain soluble accelerators, activators, and sulfur that completely dissolve in rubber giving a truly homogeneous compound.<sup>10</sup> In practice, this is achieved by selecting accelerators and activators that have a fairly high solubility in rubber at room temperature. Suitable accelerators for soluble EV include diphenyl guanidine, tetrabutylthiuram disulphide and *N*-oxydiethylenebenzothiazole-2-sulphenamide. Zinc oxide is insoluble in rubber, but it has to be included in the system as it plays a major role in sulfur vulcanization. However, 2-ethyl hexanoic replaces the common coactivator stearic acid as the latter reacts with zinc to form an insoluble zinc stearate which induces creep and the former forms a rubber-soluble zinc salt. The sulfur dosage employed in soluble EV must not exceed 0.8 pphr (parts per hundred of rubber) to ensure that it remains dissolved in the rubber and with no tendency to bloom to the rubber surface.

Nonsulfur vulcanization such as the peroxide vulcanization system produces carbon-carbon type of crosslink that gives excellent heat aging resistance and very low compression set. However, the mechanical strengths are lower than polysulfidic and monosulfidic crosslinks. The choice of vulcanization system depends on the service environment as well as the mode of deformation for the intended rubber product.

### 3.33.5 Rubber-to-Metal Bonding – Engineering and Automotive Applications

Most of the rubber springs involve bonding of rubber to metal. In many cases the metal parts are required for fixing purposes, particularly those of automotive components such as rubber bushes, engine mounts

**Table 7** Sulfur vulcanization systems, types of crosslink produced and their effect on technological properties

<i>Vulcanization system</i>	<i>Sulfur</i>	<i>Accelerator</i>	<i>Type of crosslink</i>	<i>Technological properties</i>
Conventional	2.0–3.5	1.0–0.4	Polysulfidic	Increase tensile and tear strengths, high compression set, and poor heat aging
Efficient (EV)	0.3–0.8	6.0–2.5	Monosulfidic	Excellent heat aging, low compression set, low tensile, and tear strengths
Semi-EV	1.0–1.7	2.5–1.0	Mixtures of poly, di- and mono	Compromise or balance in terms of strength and heat aging

and couplings. **Figure 6** shows some typical rubber-to-metal bonded products. In tank lining, the main function of rubber is to protect the metal against attack by corrosive chemicals as well as to protect the metal parts from oxidation by air and moisture, which leads to rusting.

The laminated rubber bearing consists of alternate layers of metal plates. The metal plates serve to restrain the lateral expansion of the rubber on compression. Because of restriction at the rubber metal interface, due to friction or when the rubber is bonded to metal, the rubber bulges at the end plates to maintain a constant volume. As a result, the effective compression modulus is dependent on the shape factor,  $S$ , defined as the ratio of loaded area to force free area.<sup>2</sup>

$$S = \text{Loaded area/Force free area} \quad [3]$$

For a rectangular rubber block of length  $L$ , width  $W$  and thickness  $h$ , shape factor  $S$  is given by eqn [4]:

$$S = LW/[2b(L + W)] \quad [4]$$

The dependence of the compression modulus on the shape factor has a significant advantage where the vertical stiffness increases substantially, by inserting horizontal metal spacer plates into the rubber. For a rectangular rubber block having length  $L$ , width  $W$  and height  $h$ , the shear stiffness and compression stiffness are given by eqns [5] and [6] respectively.

$$k_s = GA/b \quad [5]$$

$$k_c = 3G(1 + 2S^2)A/b \quad [6]$$

Here,  $G$  is the shear modulus of the vulcanizate and  $A$  is the cross-sectional area of the rubber surface subjected to shear or compression. Equation [6] shows

Rubber bearing

**Figure 6** Rubber-to-metal bonding products – (a) tank lining (LHS), (b) various automotive rubber products (RHS) and (c) below rubber bridge bearing.

that the compression stiffness can be increased substantially by increasing the shape factor. The shape factor does not affect shear stiffness. For these reasons, laminated steel rubber bearings are used in bridges, where high compression stiffness is necessary to support all dead and live loads of the deck, and very low shear stiffness to accommodate movements associated with thermal expansion and contraction due to temperature changes.

To achieve efficient bonding at the rubber–metal interface, it is necessary that the rubber is chemically bonded to the metal surface. This is achieved in practice by following proper procedures laid down in the following section.

### **3.33.5.1 Bonding of Rubber to Metal**

#### **3.33.5.1.1 Preparation of metal plates**

The metal plates must be clean and free from any contamination such as oil, grease, protective coating, and rust. Exposing the contaminated metal surface to the vapor of a suitable organic solvent (e.g., chlorinated solvent) removes oil and grease. The next step is to remove metal oxides and rust on the metal surface, usually by the sandblasting technique or wire brushing. Apart from cleaning, sandblasting increases the surface area, which is very beneficial for strengthening the bonded area. Acid etching provides an alternative means of removing metal oxides from the metal surface.

It is very vital that the metal surface is completely free from oil, grease and rust to ensure efficient wetting of the bonding agent on the metal surface so that during vulcanization the bond formed between rubber and metal via the bonding agent is very strong. However, a few precautions need to be observed when sandblasting on the metal surface. The grit size, gun pressure and shooting distance must be correct to get the right surface topology, thus avoiding excessive wear or too little wear.

#### **3.33.5.1.2 Types of bonding agent and methods of applications of bonding agent to metal plates**

The common bonding agents for bonding rubbers to metals include ebonite solution or sheet, brass and proprietary adhesives. In the past, the bonding agent as well as the lining material for making tank lining was ebonite solution and calendered ebonite sheet. The ebonite compound contains a high amount of sulfur, about 25–35 pphr. This high sulfur content makes ebonite a hard and brittle material. Indeed ebonite is a thermoset as it is highly cross linked.

The high sulfur content of ebonite introduces high polarity that makes it a very suitable bonding agent. Despite the superior chemical resistance of ebonite, there are a few limitations such as its brittleness after cure, long cure time and potential of fire hazard due to exothermic reaction during curing, especially when a thicker lining is involved. For this reason, soft rubber linings are preferred to ebonite linings.

Brass is a very good bonding agent, and is widely used in the tire industry. Brass is coated on steel wire cords by the electroplating process. Brass-coated steel wire cords are used as breakers or belts placed underneath the tread and on top of the carcass of the green tire. During vulcanization, the sulfur forms covalent bonds with both the rubber and the component metals of the brass, leading to a very strong bond.<sup>11</sup>

In most rubber-to-metal bonded products, a proprietary bonding agent is preferred to the other two bonding agents. A proprietary bonding agent usually requires two coatings, *viz.* a primer and an adhesive cement. There are reasons why a two-coat system offers more insurance for the rubber to metal bond. The first coating known as a primer helps to eliminate corrosion in corrosion-prone metals when they are in contact with the rubber.<sup>12</sup> By using a primer, secondary cement (second coating–adhesive) that has a greater degree of bondability to the stock being used can be selected, rather than a one-coat system.<sup>12</sup> It is claimed that the two-coat system allows more metal adhesion into the primer, and more stock adhesion into the cement coat.<sup>12</sup> This results in a higher intrinsic bond with the two-coat system than a single coat system.

Bonding agents are applied by painting, spraying or dipping on treated metal parts in the form of a solution or aqueous suspension.

#### **3.33.5.1.3 Molding of rubber-to-metal bonded parts**

Finally, the dried, coated metal parts are loaded into the mold and the rubber is vulcanized in contact with these substrates by the conventional rubber molding techniques such as compression, transfer and injection molding. It is during this vulcanization process that the rubber is chemically bonded to the metal surface when the cross linking agents react with the adhesive.

However, in the case of tank lining, the method is different from the conventional rubber-to-metal bonded products. The method of applying calendered rubber sheeting onto the prepared metal surfaces is

analogous to that of applying rolls of wallpaper to the walls of a room. However, care must be taken to avoid entrapment of air between rubber and metal. The rubber sheet is laid down at the correct angle, and is rolled down into close contact with the adhesive. Applying the rubber sheet at the corner or edges of the tank is quite tricky. In practice, this is achieved by making joints at corners by inserting and rolling down an extruded rubber fillet of triangular cross-section and forming the sheet joints on top of the fillet. This technique gives to the lining a well finished appearance and reduces the danger of weak joints occurring in corners.

Upon completion of laying the rubber sheet onto the metal surface, the covered lining tank is usually allowed to rest for at least 24 h before being vulcanized. This resting period allows any air trapped between rubber and metal to diffuse, apart from enabling the adhered rubber sheet to recover and settle down before it is heated.

### 3.33.5.2 Vulcanization

It is usually done in an open steam autoclave for tanks or vessels that are small enough to go into the autoclave. When the lined vessel is too large to be accommodated in an autoclave it may be vulcanized in one of the following methods:

#### 3.33.5.2.1 Low or high pressure steam

This method is applicable to a vessel that has sufficient strength to withstand internally applied pressure. This procedure can be adopted if the vessel such as road or rail tank cars can be lined and then sealed and bolted to give a strong and steam proof pressure container. The steam pressure is passed through the lined vessel to the desired vulcanization temperature until the rubber is fully vulcanized. There are some elements of danger when dealing with high pressure steam. So it is very important that all the safety regulations are met in terms of design and material of the vessel. The work should be done under skilled engineering supervision.

#### 3.33.5.2.2 Water curing technique

This method is suitable for tanks or vessels that are too weak structurally to be put under steam pressure. Here, the lined tank is filled with water or brine. The water is heated by passing live steam into the water until it approaches boiling point. This temperature is maintained for a few hours until the rubber is fully vulcanized. Care must be taken to ensure that live steam does not impinge on the rubber lining to

avoid the occurrence of a large blister between the rubber and metal at the point of impingement. It is necessary to conserve heat by shielding the unit against draughts and cold to minimize temperature variations which would affect the uniformity of the cure.

#### 3.33.5.2.3 Hot air or ambient temperature vulcanization

This method is suitable for tanks or vessels which do not work with the methods discussed above. The choice of accelerator is very important. Ultrafast or very fast accelerator is usually used in the rubber compound. Care has to be taken to ensure that the rubber does not vulcanize prematurely (scorched) before it is applied onto the treated metal surface. One of the means to overcome the problem is to avoid mixing the accelerator and sulfur together, but to prepare sulfur masterbatch and accelerator masterbatch separately. The two masterbatches are blended together just prior to calendering, and the calendered sheet applied as soon as possible to the metal to avoid the risk of being scorched.

### 3.33.5.3 Types of Bond Failure and Possible Remedies

A rubber shear mount may be expected to deform up to 300% shear strain, and the mean shear stress acting on the rubber-to-metal bond can be as high as 10 MPa or 2/3 tons per square inch.<sup>11</sup> Steel laminated rubber bearings for bridges must have a minimum bond strength of about 9 N mm<sup>-1</sup> (MS 671, 1991).

It is important to observe the failure mode that occurs in rubber-to-metal bonded products because it throws some light and clues to the root cause of the problem. It is usual to conduct peel test to determine the interfacial bond strength between the rubber and metal. There are two basic types of bond failure either adhesive or cohesive. Adhesive failure may occur at the interfacial between the rubber and substrate, or between cement and substrate. Cohesive failure occurs within the rubber itself. There are three modes of adhesive failure.<sup>13</sup> First is called CM failure that takes place between primer and metal interface. Second is CP failure that occurs at the primer to cover cement interfacial. Third is RC failure where the bond fails at the rubber–cover cement interface. RC failures are the most common and the most difficult to solve.<sup>13</sup> There are a number of causes, which bring about these bond failures. They include the following: metal surface not cleaned efficiently due to poor cleaning procedure,

contamination of metal surface during handling, incomplete wetting of adhesive on the metal surface, variations of temperature of metal surface, precured adhesive, sweeping of adhesive during molding etc.<sup>13</sup> There are remedies to overcome these problems. First, ensure that the metal surface is free from all forms of contamination. Second, avoid contamination of metal surface during handling. Third, apply the primer and adhesive cement onto the metal surface evenly by taking care of the correct viscosity of the adhesive, and correct spraying distance and thickness of the adhesive film. Fourth, use the correct type of adhesive and follow strictly the instruction and procedure recommended by the chemical supplier.

If during the peel test, cohesive failure occurs within the bulk of the rubber, then this indicates that the interfacial bond strength between the rubber and metal plate via the bonding agent is stronger than the cohesive strength of the rubber itself.

### 3.33.6 Oxidation of Rubber

Metals oxidize in the presence of air and water and consequently they corrode, become rusty and weak. **Figure 7** shows the old version of using steel rollers to accommodate movements of the bridge deck brought about by expansion and contraction due to temperature changes.<sup>14</sup> The steel rollers corroded and suffered high wear and tear. In contrast, laminated steel rubber bearing did not show any sign of wear out after nearly twenty years of installation.<sup>14</sup> However, this does not mean that elastomeric bearing will last forever. Like metals, rubbers are also prone to corrosion. Corrosion of rubbers is associated with the aging process known as degradation. All unsaturated rubbers are subject to degradation due to the attack of heat, ultraviolet (UV) light, oxygen,

ozone etc. The more is the amount of unsaturation the more it is susceptible to degradation. The term aging as applied to rubber, covers a variety of phenomenon arising out of the factors described above. Aging properties of raw rubber differ from vulcanized rubber because of the latter's specific network structure and extra network material. When natural rubber is heat-aged in the presence of oxygen or air, it invariably loses strength, in particular its tensile strength decreases. The pattern of modulus change during aging is not so straight forward because there are two opposing reactions which can occur simultaneously. One is degradation of the molecular chains and crosslinks which causes softening; the other is additional cross linking which causes stiffening. Under any given set of aging conditions (time and temperature) either softening or stiffening reactions may predominate depending on the type of vulcanization system, type of filler and antidegradants employed in the rubber compound.

Oxygen reacts with rubber only after the rubber has been acted upon by energy. This is usually from UV light, heat or mechanical energy (flexing). This energy dislodges a hydrogen atom from the rubber molecule, resulting in the formation of a radical. The oxidation of polymer with elemental oxygen is called autoxidation because it is an autocatalytic. The rate of autoxidation is affected by temperature, the presence of catalyst and also the presence of antioxidant. When the oxygen attacks the rubber it produces hydroperoxide. The hydroperoxides break to form free radicals. This is an autocatalytic, self generated free radical process. The autoxidation process involves three main stages, namely, initiation, propagation and termination. In view of the complexity of autoxidation reaction with rubber, Bolland and Gee<sup>15,16</sup> used model olefins to study the kinetics of autoxidation. **Figure 8** shows the mechanism of autoxidation as proposed by Bolland.<sup>15,16</sup>

**Figure 7** (a) Steel roller bridge bearing and (b) steel laminated rubber bearing installed in 1955. Adapted from Mullins, L. *Proc. Rubb. in Eng. Conf.* Kuala Lumpur, 1974, pp. 1–20, with permission from the Malaysian Rubber Board.

**Figure 8** Mechanism of autoxidation of natural rubber as outlined by Bolland. Adapted from Barnard, D.; Lewis, P. M. In *Natural Rubber Science and Technology*; Robert, A. D., Ed. Oxford University Press, 1988; Chapter 13, pp 621–673, with permission from . . .

The autoxidation is initiated with the generation of free radicals due to the relatively facile homolysis of traces of peroxide present in the elastomer.<sup>17</sup> The rate of oxidation is related to the concentration of the hydroperoxide [ROOH] as shown by eqn [I] below<sup>16</sup>.

$$r_i = k_i[\text{ROOH}]^2 \quad [\text{I}]$$

The resultant free radicals react with oxygen to form the deleterious peroxides and propagate the autoxidation reaction. The rate of propagation is controlled by the hydroperoxide yields and those of decomposing. The hydroperoxide yields for a large number of olefins range from almost 100% downwards to values controlled by side reactions of the peroxy radicals, such as addition to olefinic double bonds, when hydrogen abstraction becomes relatively difficult.<sup>16</sup> Such side reactions would continue the propagation chain. However, when the value of the rate constant  $k_2$  becomes large, the reaction of alkenyl radicals with oxygen become independent of oxygen pressure. Under these conditions, rate-determining step is no longer controlled by the rate constant  $k_3$ , of the hydrogen abstraction step. Termination would occur primarily by the interaction of alkenyl radicals. Then the propagation rate is given by eqn [II] below<sup>16</sup>.

$$r = r_i^{1/2} k_2 k_4^{-1/2} [\text{O}_2] \quad [\text{II}]$$

Termination occurs solely by the mutual destruction of peroxy radicals and represented by the following rate equation<sup>16</sup>:

$$r = r_i^{1/2} k_3 k_6^{-1/2} [\text{RH}] \quad [\text{III}]$$

The outcome of this autoxidation is either chain-scission or cross-linking. If chain-scission occurs, the degraded rubber will be soft and tacky. On the other hand, if cross linking occurs the degraded rubber will be hard and brittle. In both cases, the mechanical strength of the rubber decreases markedly. Model olefins were used to study the mechanism of oxidation of NR due to complexity of the oxidation reaction in particular when the rubber is vulcanized.<sup>16</sup> The oxidation of rubber vulcanizate is technologically important since the absorption of only a small amount of oxygen (1%) by rubber vulcanizate results in a considerable change in the physical properties.

It is believed that the oxidation of natural rubber follows the same route and analogous to that of the model olefins where the polyisoprene chain undergoes scission.<sup>16</sup> An essential concept of this process is the number of molecules of oxygen absorbed per scission event. According to Bolland,<sup>15</sup> the oxidation reaction would finally lead to an alkoxy radical disproportionate to butan-2-one-4-al rather levulinaldehyde, and the vinylic radical would have to be oxidized further to the methyl ketone end group. Minute amount of certain heavy metals such as copper, iron and manganese catalyze autoxidation reactions. However, this catalytic action can be prevented by applying protective or chelating agent such as metal deactivator like *p*-phenylenediamines.

In the case of vulcanized rubber, the oxidation reaction is more complex than that of raw rubber since the various different types of crosslink (e.g., polysulfidic, disulfidic, monosulfidic, cyclic sulfides, conjugated dienes and treines, etc.) present in the network structure may affect oxidation in some way or another.<sup>16</sup> Most types of sulfur vulcanizates initially hardens on aging before degradation occurs. This hardening is due to cross linking associated with oxidative reactions of sulfur species in the network that takes place before chain scissions take place.<sup>16</sup>

Barnard and Lewis<sup>16</sup> listed out some useful and important points concerning chain scission mechanism for unprotected NR at modest temperature as follows:

- Scission occurs once approximately for every 20 molecules of oxygen absorbed.
- The scission is of the rubber chain even in peroxide or sulfur vulcanizates although concomitant crosslink can occur in the latter.
- Kinetically, scission appears to take place in the propagation step.

- Each scission event results in a stable terminal ketone group being formed on one of the new chains and a transient terminal aldehyde group on the other.

Since autoxidation results in chain scission, means and ways were introduced to determine accurately chain scissions caused by a known quantity of oxygen absorbed. A parameter known as scission efficiency  $\varepsilon$  defined as the number of molecules of oxygen absorbed which bring about one scission event<sup>16</sup> was introduced to monitor chain scission quantitatively. There are two methods either physical or chemical to monitor chain scission. The common physical methods involved measuring molecular weight reduction, stress-relaxation, sol-gel analysis, and stress-strain characteristics.<sup>16</sup> For example, in stress-relaxation method, a rubber sample of a uniform cross-section is held at a constant extension and maintained at a constant temperature. When a network is oxidized due to the cleavage of stress-supporting chains, then the stress would decay and this event would lead to occurrence of stress-relaxation. The change in moles of stress-supporting chains per gram can be calculated from eqn [7]<sup>16</sup>:

$$f_t/f_0 = N_t/N_0 \quad [7]$$

where the subscripts  $t$  and  $0$  refer to the samples after time  $t$  and time zero respectively, and  $f$  derived from the statistical theory of rubber elasticity<sup>18</sup> is given by eqn [8]:

$$f = \rho NRTA_0(\lambda - \lambda^{-2}) \quad [8]$$

where  $\rho$  is the density of rubber,  $N$  is the number of moles of stress-supporting chains per gram,  $R$  is the gas constant,  $T$  is the absolute temperature,  $A_0$  is the unstrained cross-sectional area, and  $\lambda$  is the extension ratio. Stress-relaxation method has the advantage of being able to monitor scission event continuously, and if the amount of oxygen absorbed is also known then the scission efficiency  $\varepsilon$  can be calculated.<sup>16</sup> However, on a short time scale, the decay in stress level as function of time at constant deformation and temperature is associated with the rearrangement of molecular chains and it is predominantly attributed to viscoelastic behavior of the rubber.

Almost all technical specifications of elastomeric products require passing an aging test. The use of aging tests is extremely important in assessing the service life of elastomeric products because properties of vulcanizate could change during service.

The basic principle of the test is to expose rubber test-pieces to air at an elevated temperature (70 or 100 °C) for a specified period (7 or 14 days or longer). This so-called accelerated aging test causes deterioration of rubber in air due to combined effects of oxidative and thermal aging. The tensile properties, set and hardness are measured on these samples before and after ageing. If minor changes in these properties result, long service life may be expected; if appreciable changes occur, service life may be short. However, it must be stressed here that accelerated ageing test is a useful quality control and specification tests. There are significant difficulties in predicting service life from accelerated aging test. Use of test temperatures much above the anticipated service temperature is not advisable because the correlation between the results of such tests and service performance becomes increasingly tenuous.

### 3.33.7 Ozone Cracking of Rubber

Apart from oxygen, all unsaturated elastomers are also susceptible to ozone attack although ozone concentration in the outdoor atmosphere at ground level is about 1 pphm (part per hundred million of air by volume).<sup>19,20,21</sup> However, this can be significant because the reaction of ozone with the double bond is extremely fast and causes cracking on strained rubber. The cracks appear slowly at right angle to the direction of the strain applied, that grow slowly and consequently lead to a break of the vulcanizate. Ozone being very reactive attacks the double bonds of the rubber and produces ozonide that cleaves to produce zwitterions.<sup>17</sup> The zwitterions are unstable and will breakdown to form other zwitterions. These zwitterions may react with other zwitterions to produce diperoxide compound, or react with carbonyl compound to produce ozonide. In both cases, the ultimate result is chain scission. The mechanism of ozone attack on olefin is as shown in Figure 9.<sup>17</sup>

However, there is a subtle difference between ozone cracking and auto-oxidation where the former requires a certain critical strain level ( $\sim 5\%$  for unprotected NR) for its occurrence.<sup>19,20,21</sup> The severity of ozone cracking increases rapidly with strain level. Braden and Gent,<sup>19</sup> and subsequently Lake *et al.*<sup>20,21</sup> investigated various factors affecting ozone cracking. For example, Lake and Thomas<sup>20</sup> came out with a boundary layer theory for ozone attack on rubber surface to explain the rate of ozone crack growth. According to their theory, the variation in

The zwitterion may react with other zwitterion to give diperoxide compound

Or with carbonyl compound to give ozonide

**Figure 9** Mechanism of ozone attack on olefins.

the rate of ozone attack on stretched rubber surfaces produced by changes in the air velocity and magnitude of the strain is controlled by the diffusion of ozone across the relatively stationary boundary layer adjacent to rubber surface. The boundary layer effect is important because of the readiness with which ozone is destroyed by stretched rubber.<sup>20</sup> As mentioned earlier, ozone cracking occurs only in elastomers subject to tensile stresses. Elastomeric components used in compression will crack only in the regions of the surface where tensile stresses are induced. These cracks are unable to penetrate very

far because they soon encounter compressive rather than tensile stresses. Thus ozone cracking is not a serious problem for large elastomeric components such as rubber bearings which are used in compression. Nevertheless, ozone cracks are unsightly and may initiate fatigue crack growth, which ultimately leads to mechanical failure. In view of this deleterious effect, it is necessary to carry out test on ozone resistance. The test involves exposing the stretched test-pieces (20% strain) in an ozone-rich atmosphere at a fixed temperature (23 or 40 °C) and inspecting the surfaces for cracks with the aid of a magnifying

glass at intervals of time. If cracks are not observed after completion of test, the vulcanizate is said to have good resistance to ozone cracking.

### 3.33.8 Heat Aging Resistance

Elastomers can survive over long periods in service at ambient temperatures without any measurable deterioration if the products are sufficiently thick. For a thick section of rubber, the availability of oxygen will be limited by diffusion, and components with bulky rubber layers can be considerably more resistant to elevated temperatures than thin rubber sections. For example, bearing pads of NR installed in 1890 had been examined, and although the outer 1–2 mm of rubber had degraded after 96 years of exposure to the atmosphere, the inner core of the rubber was still in good condition as shown by the photograph in [Figure 10](#).<sup>2</sup> Rubber samples taken from the interior portion were found to retain good physical properties as that of freshly prepared compounds.<sup>2</sup> At sufficiently elevated temperatures, all types of elastomer will undergo degradation. However, conventional NR vulcanizates can be used safely at 60 °C, the maximum ambient temperature likely to be encountered practice.<sup>2</sup> At temperatures of 300 °C and above, NR vulcanizates first softens as molecular breakdown

**Figure 10** Cross-sectioned view of a 100-year old bridge bearing pad showing the very small depth of penetration of atmospheric degradation. Adapted from Fuller, K. N. G.; Muhr, A. H. *Engineering design with natural rubber*, NR Technical Bulletin, 5th ed.; The Malaysian Rubber Producers' Research Association, London, 1992; pp 1–33, with permission from Tun Abdul Razak Research Centre, Brickendonbury Hertford, England.

occurs, then resinify, becoming hard and brittle.<sup>2</sup> Flammable vapor are emitted and ignition occurs. However, the rate of burning is extremely slowly for the case of large block rubber.<sup>2</sup>

In recent years, new performance demands for automotive elastomers have been proposed<sup>22</sup> to perform at high operating temperatures. This move was made to accommodate increasing concern for improved fuel economy, which resulted in a significant downsizing and redesign of the automobile. Concomitantly the engine compartment became smaller and more difficult to cool thus raising the temperature of the under hood. Current automotive elastomers are expected to perform well under a 120 °C in-service temperature at least until the life of the car.<sup>22</sup>

There is a growing expectation those future automotive elastomers to perform well in a 150 °C environment for over 100 000 miles.<sup>22</sup> This is a clear signal that specialty elastomers would find very strong markets over general-purpose elastomers for high temperature performance.

### 3.33.9 Flex Cracking

Flexing and cyclic stresses can lead to premature failure during service. There are two basic mechanisms of crack growth, (i) ozone crack growth, due to primarily chain scission, and (ii) mechanico-oxidative crack growth, due to mechanical rupture at the tip of a flaw, which is considerably facilitated by the presence of oxygen.<sup>23</sup> Both types of growth can occur under static or dynamic conditions or together. The amount of crack growth in a given time is directly proportional to the ozone concentration. The crack growth rate  $dc/dt$  of a single ozone crack under static conditions is given by [eqn \[9\]](#):

$$dc/dt = \alpha q \quad [9]$$

where  $q$  is the ozone concentration and  $\alpha$  a constant (the rate at unit ozone concentration) which is a property of the rubber.<sup>23</sup> The cyclic crack growth rate is given by [eqn \[10\]](#):

$$r = (dc/dn)_{\text{ozone}} = (F/f_f)\alpha q \quad [10]$$

where  $F$  is the time fraction of cycle for which the test-piece is strained, and  $f_f$  is the frequency.<sup>23</sup> Based on fracture mechanics approach, and assuming that the growth of naturally occurring flaws of a fatigue test has the same characteristics as that of a crack growth test, Lake and Lindley<sup>23</sup> worked out

the fatigue life of vulcanized elastomer as given by eqn [11]:

$$N_f = 1/(16BW_s^2c_0) \quad [11]$$

where  $N_f$  is the number of cycles to failure from a naturally occurring flaw of size  $c_0$ .  $B$  is the crack growth constant, and  $W_s$  is the strain energy density. Thus the fatigue life  $N$  can be predicted from known parameters of eqn [11].

### 3.33.10 Oil Absorption

An unvulcanized elastomer becomes solution when immersed in its solvent; in contrast, a vulcanized elastomer will only swell. The extent of swell depends on the amount of solvent absorbed, which in turn depends on the crosslink concentration and types of solvent. Swelling is undesirable because apart from dimensional instability, the modulus and mechanical strengths are all decreased making the

swollen vulcanizate unsuitable for most engineering applications.<sup>2</sup> In the case of rubber-to-metal bonded, bond failure occurs if the liquid is able to reach the metal plate. **Figures 11 and 12** show some of the typical automotive elastomeric components such as fuel and oil hoses, gaskets, O-rings and seals which are in contact with automotive fuels. These rubber components are thin and susceptible to damages when swollen excessively by the oil. Additives such as ethanol, methanol, and methyl *t*-butyl ether are being placed in gasoline with a view to improve its octane number.<sup>22</sup> Increasing the alcohol content of the gasoline increases the amount of swell, which is very undesirable not only because of dimensional instability, but also reduces tensile strength and elongation at break of the swollen elastomer.

It is well established that swelling is diffusion-controlled and the volume of liquid absorbed is initially proportional to the square root of the time of immersion.<sup>2</sup> For most organic liquids, the rate of penetration depends on their viscosity rather than

**Figure 11** Automotive rubber products in contact with oil and heat: (a) hoses – hydraulic, fuel, gasoline pump, and steam hose and (b) gaskets, O-rings, seals, and exhaust hanger, etc.

**Figure 12** Automotive rubber components: (a) gaskets and (b) O-rings and seals.

their chemical nature<sup>2</sup>. Figure 13 shows the time–viscosity relationship for the liquid to penetrate 5 mm into the rubber interior.<sup>2</sup>

For NR, it takes about 4 days for a volatile liquid such as toluene to penetrate 5 mm depth, 1–2 years for engine lubricating oil, and about 30 years for a petroleum jelly, even with continuous immersion.<sup>2</sup> It is possible to estimate the distance of liquid in a given time provide that the penetration rate is known.<sup>2</sup> Alternatively, the viscosity of the liquid may be used if penetration rate is not known since the penetration rate is related to viscosity as shown earlier in Figure 13.

Southern<sup>24</sup> has introduced a nomogram as illustrated in Figure 14 to facilitate the calculation in estimating the penetration depth of liquid into the elastomer. Although the data were obtained for NR, but would be expected to work with other elastomers of similar  $T_g$ .<sup>24</sup> As an illustration to use the nomogram, Southern<sup>24</sup> has calculated, a liquid with penetration rate of  $7 \times 10^{-5} \text{ cm s}^{-1/2}$  would take 4 weeks to penetrate 1 mm, but 100 years to penetrate 40 mm of the rubber block. The penetration rate–viscosity relationship does not hold for water because of the presence of hydrophilic impurities which complicate transport of water in elastomers.<sup>24</sup>

### 3.33.10.1 Effect of Crosslink Concentration and Polarity on Swelling Resistance

Natural rubber (NR) latex has found very wide applications in the glove industry since the 1920s. This is attributed to the excellent tear and puncture

**Figure 13** Effect of viscosity of liquid on penetration time. Adapted from Fuller, K. N. G.; Muhr, A. H. *Engineering design with natural rubber*, NR Technical Bulletin, 5th ed.; The Malaysian Rubber Producers' Research Association, London, 1992; pp 1–33, with permission from Tun Abdul Razak Research Centre, Brickendonbury Hertford, England.

resistance of NR latex films. Besides, NR latex film exhibits very high extensibility (600–1000%) before its breaking point. These properties make NR latex film an excellent barrier protection against infectious liquids and gases. Most of the examination and surgical NR latex gloves are used in hospitals and clinics. However, recently NR latex gloves have entered the fast food industry where good swelling resistance is an essential requirement. Being a nonpolar rubber, NR latex gloves have a poor swelling resistance which limits its application in the fast-food industry. The fast-food industry is growing very fast all over the world. There is a growing concern over the cleanliness and hygiene of the food. It is essential that the workers wear rubber gloves to avoid contact with the food they serve. Rahim and Samsuri<sup>25</sup> investigated the effect of crosslink concentration and effect of blending carboxylated nitrile rubber (XNBR) with NR latex on the swelling resistance of NR latex film towards cooking oil. The amount of sulfur was varied to produce different crosslink concentrations. The crosslink concentration was determined by immersing the latex film sample in a solvent until equilibrium swelling was attained. The crosslink concentration was calculated by using the Flory–Rehner equilibrium swelling equation as proposed by Mullins<sup>18</sup> given by eqn [12]:

$$-\ln(1 - v_r) - v_r - \chi v_r^2 = 2\rho V_1 [X]_{\text{phy}} v_r^{1/3} \quad [12]$$

where  $v_r$  is the volume fraction of rubber in the swollen gel,  $\rho$  is the density of rubber,  $V_0$  is the molar volume of solvent,  $\chi$  the rubber–solvent interaction parameter, and  $[X]_{\text{phys}}$  is the physically manifested crosslink concentration. The diffusion coefficient  $D$  was calculated from eqn [13]<sup>24</sup>:

$$M_t/M_\infty = (2/l)(Dt/\pi)^{1/2} \quad [13]$$

where  $M_t$  is the total amount of liquid absorbed per unit area of the sheet after immersion for time  $t$ ,  $M_\infty$  is the amount of liquid absorbed after infinite time (in this case time to reach equilibrium swelling), and  $l$  is the half thickness of the film sheet. It is necessary to plot  $M_t$  against square root time as shown in Figure 15 to calculate  $D$  in eqn [13].

The effect of crosslink concentration on the diffusion coefficient of cooking oil in the latex film is shown in Table 8.<sup>25</sup> The results show that increasing the crosslink concentration decreases the diffusion coefficient significantly. Increasing the sulfur content from 0.6 to 3 pphr increases the crosslink concentration by about 90%, which merely decreases the

**Figure 14** Nomogram to facilitate rapid calculation of distance penetrated by liquid into rubber. Adapted from Muniandy, K.; Southern, E.; Thomas, A. G. In *Natural Rubber Science and Technology*; Robert, A. D., Ed.; Oxford University Press, Oxford, UK, 1988; Chapter 13, pp 820–851, with permission from Oxford University Press.

diffusion coefficient by about 23%. However, the most efficient method to increase swelling resistance is through physical blending of NR latex with XNBR latex, where the diffusion coefficient  $D$  of the oil into the film decreases by a factor of 2.7 compared with NR latex having the highest crosslink concentration. Thus, this work shows strong evidence that blending of nonpolar elastomer with polar elastomer enhances the swelling resistance of the former.

### 3.33.11 Water Absorption

Elastomers find wide uses in marine and offshore engineering applications. The application of elastomers

in water management is attributed to its high impermeability to water. A rubber sheet is used to line the water reservoir and pond, while inflatable rubber is used as a dam. Rubber dock fenders rely on the energy absorption capacity of the rubber. Inevitably, the rubber will absorb some quantity of water as these rubber products spend a considerable time under water. It is of great concern whether the absorption of water would impair the strength of the rubber.

The true solubility of water in rubber is very low.<sup>24</sup> Nonetheless, relatively large amounts of water can be absorbed during prolonged immersion as shown in [Figure 16](#).<sup>2</sup> The diffusion of water in elastomers is not straightforward, but complicated by the presence of hydrophilic materials. In the case of NR it is mainly

**Figure 15** Typical mass uptake curve for NR/XNBR blend latex film.<sup>25</sup>

**Table 8** Effect of crosslink concentration on diffusion coefficient  $D$  of cooking oil into NR latex film

Sulfur level (pphr)	$[X]_{phy}$ (mol per kg RH)	$D$ ( $m^2 s^{-1} \times 10^{-13}$ )
0.6	$4.46 \times 10^{-2}$	4.70
1.0	$4.60 \times 10^{-2}$	4.00
2.0	$4.89 \times 10^{-2}$	3.70
3.0	$5.82 \times 10^{-2}$	3.57

proteinaceous.<sup>24</sup> When water diffuses into the rubber, the water-soluble hydrophilic materials dissolve forming droplets of solution within the rubber. Osmotic pressure gradient would exist between watery domains in the rubber and that of the external solution immersing the rubber.<sup>24</sup> This results in more water diffusing into the internal solution droplet. Water absorption reaches its equilibrium when the elastic stresses acting on the droplets balance the osmotic pressure difference. Muniandy and Thomas<sup>24</sup> proposed a mathematical model for water absorption to derive equations for the equilibrium water uptake and to evaluate the kinetics of water absorption and desorption. From the model, they calculated the equilibrium water uptake and the apparent diffusion coefficient. They found very good agreement between theory and experimental results.

**Figure 16** Corrected mass uptake measurements for engineering rubbers in seawater at 23 °C: (a) deproteinized NR, (b) lead oxide cured polychloroprene, (c) nitrile rubber, (d) conventional NR, and (e) conventional polychloroprene. Adapted from Fuller, K. N. G.; Muhr, A. H. *Engineering design with natural rubber, NR Technical Bulletin*, 5th ed.; The Malaysian Rubber Producers' Research Association, London, 1992; pp 1–33, with permission from Tun Abdul Razak Research Centre, Brickendonbury Hertford, England.

Later, Lake<sup>26</sup> investigated the kinetics of water (tap water) absorption in elastomers and their effects on properties. He reported that when the absorption was large (50% or more), the rubber test-piece degraded. Severe degradation leads to porosity of the surface layer, and when pressed, water exudes.<sup>26</sup> However, at a low level of absorption, Lake observed

**Figure 17** A natural rubber tire after 40 years' exposure to seawater. Adapted from Mullins, L. *Proc. Int. Rubb. Conf.* Kuala Lumpur, 1985, with permission from Malaysian Rubber Board.

the formation of droplets similar to the blisters that occur in plastics or under protective coatings, consistent with an osmotic diffusion mechanism.<sup>24</sup> In salt-water, water absorption reached steady state at much lower levels than in freshwater, again consistent with an osmotic pressure mechanism. Thus seawater is less damaging than freshwater and may not have any serious consequences for many elastomers. This latter point is consistent with findings of Ab. Malek and Stevenson<sup>27</sup> who evaluated the physical properties of a rubber tire as shown in [Figure 17](#), recovered from seawater at a depth of 80 ft. They found that the rubber tire had absorbed about 5% of seawater after 42 years of immersion. They found no evidence of microbiological attack. What is more interesting, the physical properties of the rubber tire were within normal specifications for new rubber of the same type. They even suggested storing elastomers in deep seawater in view of its inert nature. Indeed, elastomer is a very suitable material to coat metal surfaces against corrosion in deep seawater. The photograph in [Figure 17](#) shows clear evidence that the steel cords making up the bead of the tire are corrosion-free after a 42-year immersion in seawater.<sup>27</sup>

### 3.33.12 Protective Measures

#### 3.33.12.1 Selection of Elastomer

All elastomers experience aging. Some age faster than others. The rate of aging depends on a number of factors such as the chemical structure of the polymer, service environment, which includes length of exposure to heat and light, oxygen and ozone concentration, size and shape of elastomers, and mechanical

stresses. One cannot stop the aging process, but one can slow it down. The most effective means of combating aging is to select the correct elastomers to meet the maximum service temperature and environment. Fully saturated elastomers having high bond dissociation energy making up their backbone chains are the best choice to meet high service temperature applications. Fully saturated rubbers such as ethylene propylene copolymer and very low unsaturation butyl rubber are excellent resistance to heat aging, oxidation and ozone cracking. Not only the maximum service temperature, but also other environmental factor such as oil or solvent determines the aging resistance. In cases like these, the elastomers having high bond dissociation energy and solvent resistance are desired. These include specialty elastomers such as acrylic (ACM), chloro-sulfonyl-polyethylene (CSM), ethylene propylene copolymer (EPM), fluoroelastomers (FKM), silicones (MQ, VMQ), polyester urethanes (AU), etc. Alternatively, for unsaturated elastomers are to use antioxidants and antiozonants, with correct vulcanization system can slow down the aging process quite efficiently.

#### 3.33.12.2 Blends of Elastomers

It is a common practice to blend two elastomers of different properties with a view to combining the best features in terms of technical and economic values. Natural rubber is blended with EPM for applications requiring very high resistance to attack by ozone as the latter is fully saturated. A blend of NR and EPDM is used for applications that require a combination of good resistance to attack by ozone and high

strength properties. Nitrile rubber (NBR) is blended with EPM to meet the requirements for very good oil resistance as well as conferring high resistance to oxidation and ozone cracking. The former is polar rubber and provides very good oil resistance, while the latter provides excellent weather resistance. However, blending two or more elastomers is not as easy as one would imagine. The work on blending various elastomers conducted by Tinker<sup>28</sup> and coworkers has thrown some light on the importance of compatibility, distribution of crosslinks in each rubber phase, distribution of filler and plasticizer and interfacial tension of each phase which have very strong influence on the service performance of the blend. When the elastomers are not compatible with each other, the associated problems that may arise include maldistribution of crosslinks, partition of chemicals (sulfur, accelerators, etc.) due to mechanism associated with preferential solubility and others. Lewan<sup>29</sup> worked on crosslink density distribution in NR/NBR blend and reported the effects of large difference in polarity and solubility parameters between these two rubbers. The large difference in polarity has the following effects:

- (i) causes high interfacial tension that is detrimental to mixing since it interferes with efficient mixing at the interface, hence minimizing the opportunity for crosslinking between the rubbers;
- (ii) causes poor phase morphology, which is characterized by large phase sizes;
- (iii) causes uneven distribution of crosslinks arises through preferential solubility of the curatives and vulcanization intermediates. Sulfur will be preferentially soluble (partition in favor of) the more polar NBR. One phase is over-crosslinked and the other is lowly crosslinked.

However, Lewan<sup>29</sup> overcame these problems by selecting the correct type of curing system such as semi-EV based on sulfur – TBBS, to obtain an even distribution of crosslinks in each phase and maximizing crosslinking between rubbers at the interface. The use of compatibilizer is highly recommended to enhance the compatibility between rubber phases. Polychloroprene rubber serves as a very good compatibilizer for the NR/NBR blend with just a small quantity (5 pphr) added to the blend. The addition of this compatibilizer reduced phase sizes, gave an even distribution of crosslinks and increased tensile strength.<sup>30</sup> Blends of elastomers provide alternative means of improving both aging resistance and oil resistance.

### 3.33.12.3 Antidegradants

Chemical antioxidants and antiozonants combat aging by scavenging harmful radicals, absorbing UV light, deactivating catalytic metals like copper, manganese, iron, etc., and decomposing initiating peroxides.<sup>16,17</sup> Two main types of chemical antioxidants and antiozonants are widely used in rubber compounds; they are amines and phenolics. Amine types are more effective and powerful antioxidants than phenolic types. However, the former is staining and the latter is not. Thus, this limits applications of amine types to black and dark colored elastomeric products. Phenolic types are exclusively used for white and bright colored products, especially in electrical wire insulation where colors are useful for identification purposes. Both amines and phenolics provide protection against aging by scavenging the harmful free radicals during the oxidative chain reaction.<sup>16,17</sup> The proposed mechanism<sup>17</sup> by which these two types of antioxidants work is shown in **Figure 18**. During the initiation stage, the free radicals produced by the peroxides abstract a labile hydrogen atom from the antioxidant and produce an antioxidant radical. This antioxidant radical is more stable than the peroxy radical, which terminates by reaction with other radicals in the system.<sup>16,17</sup>

The transfer step (c) and termination step (f) remove the free radical functionality from the elastomer, which consequently halts the oxidative degradation reaction.<sup>17</sup> Metal deactivators such as 2-mercaptobenzimidazole and its salt when added into the rubber compound containing amine or phenolic antioxidant give a synergistic effect to enhance the protection against aging.<sup>31</sup> These chemicals form

**Figure 18** Mechanism of amine and phenolic antioxidant activity, where AH is the antioxidant.<sup>17</sup>

coordination complexes with catalytic metals and inhibit metal-activated oxidation. Carbon black is a natural UV light absorber, and for nonblack compounds, it is useful to incorporate a UV light absorber such as benzotriazole derivative.

### 3.33.12.3.1 Mechanism of antiozonant action

The mechanism by which an antiozonant protects unsaturated rubber against ozone cracking has received attention from many rubber chemists and physicists. A number of suggestions have been proposed as to how antiozonants confer protection, ranging from competitive reaction with ozone (scavenging) to various types of protective layer formation.<sup>17,19–21</sup> There are three theories to describe the mechanism of antiozonant action<sup>17</sup>:

- (i) The antiozonant blooms to the surface of the rubber compound and reacts preferentially with the incident ozone.
- (ii) The antiozonant blooms to the surface of the rubber and forms a protective layer of film on the surface.
- (iii) The antiozonant reacts with intermediates formed in the ozonation of rubber, preventing chain scission or recombining severed rubber chains.

Lake<sup>32</sup> has conducted some work to elucidate the mechanism of antiozonant action to protect natural rubber against ozone cracking. He used dioctyl-*p*-phenylenediamines (DOPPD) antiozonant for his rubber compound. Exposing the rubber test-piece to ozone-rich atmosphere has reportedly resulted in a layer of film  $10^{-3}$  cm thick and visible to the naked eye forming on the rubber surface.<sup>32</sup> The protective layer can be removed by physical means either by scraping or using adhesive tape, or by swabbing with cotton wool dipped in acetone. The mass of the film can be determined by weighing the test-piece before and after its removal. In this way, the kinetics of layer formation can be determined by monitoring changes in weight after various periods of exposure to ozone.

Lake<sup>32</sup> has derived a mathematical expression to relate the mass of layer per unit area of surface  $M_L$  formed after time  $t$  to the concentration  $C_0$  of antiozonant in the rubber and diffusion coefficient  $D_L$  as shown by eqn [14]:

$$M_L = [2\rho_L D_L S_L C_0 t]^{1/2} \quad [14]$$

where  $\rho_L$  is the density of the layer material and  $S_L$  is the solubility, relative to that in the rubber, of the antiozonant in the layer. In deriving this equation,

Lake<sup>32</sup> assumed that the layer to be formed entirely of reacted antiozonant and the concentration of unreacted material within it to be small. The product  $D_L S_L$  was determined experimentally by measuring the rate of transfer of antiozonant through the layer formed on a test-piece to a controlled rubber test-piece containing no antiozonant initially. This was done experimentally by pressing two cylindrical discs (test-piece A contains antiozonant, test-piece B has no antiozonant) together so their surfaces are in intimate contact with each other. The antiozonant from test-piece A would migrate into test-piece B as a function of time. The mass of the layer formed per unit area of surface was plotted against the square root of time to produce a straight line whose slope gave the value of  $M_L/t^{1/2}$ , that is mass of film deposited per square root time. Lake<sup>32</sup> obtained very good agreement between theory and experimental data.

Lake<sup>32</sup> proposed the mechanism of antiozonant action as follows: The protective layer formed on the rubber surface is composed predominantly of the antiozonant which has reacted with ozone. The film formed remained essentially in the unstrained state, independent of the type of deformation applied. For this to happen, it is necessary that the antiozonant is soluble in the rubber, and that its reaction product should be insoluble. However, once the protective layer becomes coherent and compact, it will reduce substantially the flux of ozone reaching the rubber surface. Thus it appears that the ability of the antiozonant to prevent cracking is likely to be determined by what occurs during the initial stages of exposure when the layer is starting to form, rather than by the long-term behavior. Indeed, Lake<sup>32</sup> suggested that a coherent monomolecular layer of film that formed on the rubber surface is sufficient to confer protection against ozone cracking. However, the time for this monolayer to form must be faster than the time for the crack to grow to the same depth, so that the monolayer is able to bridge any cracks that have begun to grow.

### 3.33.12.3.2 Theories of layer formation

The thin layer of protective film covering the rubber surface is a direct consequence of the chemical reaction between chemical antiozonant and ozone. Lake and Mente<sup>21</sup> proposed two diffusion models to work out a theory for layer formation. The two models are shown in Figure 19. The first model describes the rate of layer formation that is controlled by the diffusion of the antiozonant across the already-formed layer to react with ozone at its outer surface. Under

**Figure 19** Diffusion models for antiozonant layer formation: (a) rate governed by diffusion of antiozonant within the layer only, and (b) rate governed by both diffusion in the layer and in the rubber. Adapted from Lake, G. J.; Mente, P. G. *J. Nat. Rubb. Res.* **1992**, 7(1), 1–13, with permission from Malaysian Rubber Board.

these circumstances, the mass per unit area  $M_L$ , of layer formed after time  $t$  is given by eqn [14].<sup>21,32</sup> The concentration gradient in the layer will be essentially linear as shown in Figure 19(a). The second diffusion model takes into account diffusion within the rubber in addition to diffusion across the layer. In this case, an equation similar to eqn [14] applies, when  $C_0$  is replaced by  $C_s$ , the concentration at the rubber surface is lower than  $C_0$  as shown schematically in Figure 19(b).  $C_s$  is a function of  $C_0$  and the relative permeabilities of the rubber and the layer to the antiozonant, and with the assumptions made, are given by eqn [15]:

$$C_s/C_0 = 1 + \xi - [(1 + \xi)^2 - 1]^{1/2} \quad [15]$$

where

$$\xi = (\pi/4)(\rho_L D_L S_L / D C_0) \quad [16]$$

and  $D$  is the diffusion coefficient of the antiozonant in the rubber. The mass of layer per unit area of surface plotted against square root of time as shown in Figure 20 enabled Lake and Mente<sup>21</sup> to determine the rates of layer formation of the antiozonants formed on NR, ENR 50, and NBR 34, respectively. These three rubbers differ greatly in terms of

**Figure 20** Dependence of the mass of antiozonant layer formed on the square root of the time of exposure to an ozone concentration of 200 pphm at 40 °C for vulcanizates of NR, ENR 50, and NBR 34. Adapted from Lake, G. J.; Mente, P. G. *J. Nat. Rubb. Res.* **1992**, 7(1), 1–13, with permission from Malaysian Rubber Board.

polarity and glass-transition temperature, which may affect the rate of film formation on the rubber surface. Their experimental results as shown in Figure 20 indicate that the rate of layer formation for NR is about four times faster than that of NBR 34 and ENR 50, which is in accordance with the dependence of the diffusion coefficient on the glass-transition temperature of the rubber. The diffusion coefficient decreased in the increasing order of the  $T_g$  of the rubber.<sup>21</sup> Thus the diffusion coefficient of NR is fastest and that of ENR 50 is the slowest as  $T_g$  of NR is about  $-69$  °C and that of ENR 50 is about  $-24$  °C.<sup>21</sup> NBR34 has a slightly faster diffusion coefficient than ENR 50 as its  $T_g$  ( $-28$  °C)<sup>19</sup> is slightly lower than that of ENR 50. Lake and Mente<sup>21</sup> also conducted experiments to investigate the effect of temperature on layer formation on the NR surface at  $-17$  and  $23$  °C respectively as shown in Figure 21. They found that the rates of layer formation at these two temperatures were the same for NR. However, the diffusion coefficient of this particular antiozonant (DOPPD) in NR at  $-17$  °C was very similar to that in ENR 50 and NBR 34 at  $23$  °C. They attributed this finding to the partitioning of the antiozonant

**Figure 21** Mass of antiozonant layer formed versus square root of the time of exposure to  $10^5$  pphm ozone for an NR vulcanizate containing 10 phr DOPPD at 23 and  $-17^\circ\text{C}$ . Adapted from Lake, G. J.; Mente, P. G. *J. Nat. Rubb. Res.* **1992**, 7(1), 1–13, with permission from Malaysian Rubber Board.

between the elastomer and the layer material, as the polarity of the elastomer affects the solubility of the antiozonant in the rubber. The solubility of the antiozonant varies in the ascending order of polarity of elastomer, that is  $\text{NR} < \text{NBR } 34 < \text{ENR } 50$ .<sup>21</sup> Lake and Mente concluded that for elastomers with high  $T_g$ , the antiozonant offers better protection at temperatures above room temperature than at low temperature, as the protective agents are more mobile at high temperatures rather than at low temperatures.

### 3.33.12.4 Blooming of Wax

Besides chemical antiozonants, paraffin wax is also a useful ingredient to confer protection against ozone cracking. Wax provides a protective layer surrounding the surface of the elastomer through the diffusion process commonly known as blooming, which prevents direct contact between ozone and the elastomer. Blooming occurs when the supersaturated solution of the ingredient in the rubber crystallizes more readily on the surface than in the rubber itself.<sup>24,33</sup> This basic mechanism of blooming is not only applicable to wax but other ingredients as well. When other ingredients such as sulfur, accelerators and stearic acid bloom to the rubber surface, they reduce the tackiness of the rubber, which can bring detrimental effects to

products relying on adhesion and bond strength involving different components plied together. These include rubber-to-metal bonded components, tires, belts, and hoses. However, blooming of waxes and antioxidants brings advantages.

Nah and Thomas<sup>33</sup> investigated the mechanism and kinetics of diffusion of wax to the rubber surface. They envisaged that the driving force for the blooming process arises from the elastic forces acting around the wax precipitates in the rubber when the wax concentration is in excess of its equilibrium solubility. They then proposed a model and theory for wax blooming base on thermodynamic concept of diffusion, where the driving force of the diffusion process is predominantly associated with free energy gradient rather than the concentration gradient of the wax that is dissolved in the rubber. The initial rate of wax bloom per unit area ( $M_t/t^{1/2}$ ) is given by eqn [17]<sup>33</sup>:

$$(M_t/t^{1/2})_{x=0} = [(24v_f D_t s_x \rho_x V_x G)/RT]^{1/2} (d\lambda/dy)_0 \quad [17]$$

where  $D_t$  is diffusion coefficient,  $v_f$  is volume fraction of seeding particles or flaws present in the rubber.  $s_x$  is solubility of wax in the rubber,  $\rho_x$  is density of wax, and  $V_x$  is molar volume of solid wax.  $G$  is shear modulus of the rubber,  $R$  is molar gas constant,  $T$  is absolute temperature.  $(d\lambda/dy)_0$  is equivalent to the concentration gradient of the wax at the surface of the rubber, and is determined by numerical methods for the appropriate boundary conditions and a suitable value of  $v_f$ . The symbol  $\lambda$  stands for the extension ratio of the rubber around the precipitated wax particle, assumed spherical. Nah and Thomas<sup>33</sup> verified eqn [17] experimentally, and obtained satisfactory agreement between their experimental and theoretical values for the migration of paraffin waxes in peroxide cured natural rubber. The theory was applicable to predict the blooming of wax mixtures with success, indicating that the mechanism of wax blooming has been identified correctly. Although Nah and Thomas developed the theory for blooming of wax, with minor adjustments, it is also applicable to predict migration and blooming of sulfur, fatty acids and antidegradants in vulcanized elastomers.

### 3.33.12.5 Choice of Vulcanization System

Anaerobic aging usually decreases the stiffness, resilience, and tensile, tear and fatigue properties; the extent is mainly determined by the type of vulcanization system, which affects aging of elastomers. There are three types of sulfur vulcanization systems known as conventional, efficient (EV) and

semi-efficient (semi-EV) respectively<sup>8,10</sup> as discussed briefly in [Section 3.33.4.3](#). The conventional system has a higher sulfur dosage than the accelerator that produces predominantly polysulfidic crosslinks, where the rubber molecular chains are linked by three or more sulfur atoms. Polysulfidic crosslinks have poor resistance to heat aging because the  $-S-S-$  bond has low thermal stability. In contrast, EV makes use of the low sulfur level and high accelerator dosage. This EV system produces predominantly monosulfidic crosslinks which are thermally very stable. The rubber network consists of other structural features as described briefly in subsequent sections.

### **3.33.12.5.1 Sulfur vulcanization system and types of crosslinks on aging resistance**

#### **Polysulfidic crosslink**

A chain of three or more sulfur atoms (maximum of six atoms) in this crosslink bridges two polymer chains. The bond energy of this crosslink is less than  $268 \text{ kJ mol}^{-1}$ , which is relatively low.<sup>10</sup> A polysulfidic crosslink can be produced by using the conventional vulcanization system where the quantity of sulfur is more than the quantity of the accelerator in the ratio 5:1 (sulfur: accelerator). Therefore the conventional sulfur cure system is not suitable for high temperature applications.

#### **Disulfidic crosslink**

In a disulfidic crosslink, there are two sulfur atoms bridging the two polymer chains. Its bond energy is about  $268 \text{ kJ mol}^{-1}$ . Little is known of the properties of this crosslink, mainly because it is very difficult to prepare a network in which disulfides are predominant. In both conventional and efficient sulfur vulcanizes the proportion of disulfidic crosslink is seldom more than 20–30% of the total.

#### **Monosulfidic crosslink**

In the case of a monosulfidic crosslink, the two polymer chains are bridged by one sulfur atom. Its bond energy<sup>10</sup> is relatively high, about  $285 \text{ kJ mol}^{-1}$ . A monosulfidic crosslink can be produced from an EV system where the amount of the accelerator is higher than the amount of sulfur, about 5:1 (accelerator:sulfur). Thus the EV system is suitable for medium high temperature applications.

#### **Cyclic sulfides**

These are intra-crosslinks which are useless as the crosslinks are formed on the same polymer chain.

This phenomenon is also known as main chain modification. The main source of these main chain modifications is the thermal decomposition of polysulfide crosslinks. The conventional vulcanization system creates more cyclic sulfides than the EV system as the former produces more polysulfide crosslinks than the latter.

#### **Conjugated diene and triene groups**

These main chain modifications are also formed by the thermal decomposition of polysulfide crosslinks. The concentration of these conjugated groups increases on overcure. The presence of these groups tends to catalyze oxidative aging as they are much more susceptible to oxidation than the polyisoprene main chain.<sup>8,10,16</sup>

#### **Pendent accelerator group**

It is generally accepted that in accelerated sulfur vulcanization, crosslinks are formed from initial rubber-bound pendent groups in which disulfide or polysulfide chains are terminated by accelerator fragments. Like the crosslink, some of these intermediates undergo progressive desulfuration and are converted into stable monosulfidic links between the polymer chain and accelerator fragments. The extent of main chain modification will depend on the amount of accelerator available and on the ease with which the initial pendent group can be desulfurated.

#### **Extra-network material**

The extra-network material formed by a sulfur vulcanizing system can be put into two categories. The first consists of unreacted zinc oxide and fatty acid activators, their zinc soap reaction products and zinc sulfide. The second consists of accelerator reaction products.

### **3.33.12.5.2 Peroxide vulcanization system**

Unlike sulfur vulcanization, peroxide vulcanization does not require the presence of double bonds. In fact, peroxide vulcanization is possible for rubbers having either saturated or/and unsaturated carbon-carbon backbone chains. However, peroxide vulcanization is quite impossible with the following elastomers because of their tendency to decompose:

- IIR – butyl rubber
- CIIR – chlorinated butyl rubber
- CO – polyepichlorohydrin rubber
- ECO – copolymer of epichlorohydrin and ethylene oxide
- PP – polypropylene
- ACM – polyacrylic rubber

The most common peroxide is dicumyl peroxide (DCP or dicup). Others include ditert butyl peroxide, dibenzoyl peroxide and bis(2,4-dichlorobenzoyl) peroxide. Peroxide vulcanization<sup>10</sup> produces a vulcanizate which will impart good aging resistance and excellent resistance to compression at high temperatures (70–100 °C). To obtain the best compression set performance, freedom from certain other compounding ingredients, especially zinc oxide and stearic acid, is essential. Peroxide vulcanization is essentially nonreverting. However, there are certain deficiencies such as poor hot tear strength and incompatibility with chemical antiozonants. Other technical limitations include slow cure rate with no delayed action, and degradation of the rubber giving a sticky surface if it comes into contact with air during the cure. Thus peroxides are not suitable for hot-air or steam-pan curing. The reaction of peroxide must be carried through to completion to obtain the best heat resistance; therefore long cure times are inevitable. In addition, nearly all antidegradants and aromatic oils affect the efficiency of the peroxide cure.

Co agents, which are highly reactive materials, are usually added in peroxide vulcanization to increase the efficiency of the organic peroxide, but do not affect the rate of cure.<sup>10,31</sup> They are used either to enhance the modulus and hardness or to reduce the level of peroxide required. They can be absolutely essential for the efficient cure of chlorinated polyethylene. Typical solid coagents are zinc diacrylate, zinc dimethacrylate, and *m*-phenylene dimaleimide. Liquid coagents are materials such as triallyl cyanurate (TAC), triallylisocyanurate (TAIC), etc. High vinyl polybutadiene is a polymer which can act as a coagent.

### 3.33.12.5.3 Vulcanization with urethane

This (urethane) crosslinking system for natural rubber was developed in the early 1980s by the scientists at the Malaysian Rubber Producers Research Association (MRPRA).<sup>10,31</sup> It was marketed under the trademark Novor. The basic reagent is a reaction product of a nitroso compound and a diisocyanate which dissociates at vulcanizing temperatures into its component species. The free nitroso compound then reacts by addition to rubber molecules giving attached pendent groups which subsequently react with the diisocyanate to form urea type crosslinks. The main features of the vulcanizates are excellent reversion resistance and, when protected with a TMQ/ZMBI antioxidant combination, excellent heat aging resistance.

### 3.33.12.5.4 Metallic oxide vulcanization

Elastomers containing halogens can be cured with metallic oxides such as oxides of zinc, magnesium, and lead. The oxides form an ether type of crosslink (R–O–R') which gives good heat aging resistance. Elastomers which can be vulcanized with metallic oxides are polychloroprene, halogenated butyls, and polychlorosulphonated rubber.

### 3.33.12.5.5 Resin vulcanization

Resin vulcanization has established itself to some degree in butyl (IIR) crosslinking, giving excellent heat and steam stability.<sup>10</sup> Example of a typical resin cross linker is polymethylolphenolic resin. The amount used is at the level of 5–12 pphr.

### 3.33.12.5.6 Quinonedioximes vulcanization

*p*-Benzoquinonedioxime (CDO) as well as its dibenzoyl derivative are cross linkers for many rubbers because of their free radical reactions.<sup>10</sup> Best known and of greatest interest is their use in IIR because of the excellent heat and steam stability that can be obtained. They are used mainly for rubbers having low unsaturation where sulfur vulcanization is slow. They have been unimportant for the classic diene rubbers.

## 3.33.13 Future Developments in Materials or Applications

Natural rubber and synthetic elastomers are likely to maintain their roles and contributions in domestic and industrial applications, buildings and structures, automobiles, and marine and engineering products. With the emergence of nanomaterials for rubber compounding, it is envisaged that future elastomeric products will provide better service and longer life performance than they are capable of providing now. High heat resistant elastomers and highly oil resistant elastomers are the main players of the future to meet the high demands of the automotive industry and aeronautical engineering. More developmental work in these areas is expected.

## Acknowledgements

I am very grateful to Dr. Stuart Lyon, Reader in Corrosion Control Engineering, School of Materials (Corrosion and Protection Centre), University of Manchester, England, who gave me the opportunity to write as part of the prestigious Shier's Corrosion

book. I feel much honored to be among the experts who contributed to this fourth edition of Shier's Corrosion.

It gives me great pleasure to thank the Publication Divisions of the Malaysian Rubber Board (MRB) (formerly Rubber Research Institute of Malaysia), and its sister concern the Tun Abdul Razak Research Centre (TARRC) (formerly Malaysian Rubber Producers Research Association) at Brickendonbury Hertford, England. In particular, Dato' Dr. Kamarul Baharin Basir, Director General, MRB and Mdm Rabeatun Awaliah Awalludin, MRB, and Dr. A.J. Tinker (Director Research) TARRC and Ms. K. Lawson TARRC who helped me to obtain the permission to reproduce data and figures from their respective Publication Divisions.

I would like to express my sincere appreciation and thanks to Oxford University Press and the American Chemical Society (Rubber Division) for giving permission to reproduce figures and data from their respective publications.

Last but not least, Associate Prof. Dr. Mohamad Kamal Harun, Dean of Faculty of Applied Sciences, MARA University of Technology, Malaysia (UiTM) for his encouragement.

## Glossary

### Damping Basic property of an

elastomer to dampen, absorb or reduce vibrations. High damping elastomers are those having high glass-transition temperature ( $T_g$ ), which are widely used to isolate vibrations.

**Glass-transition temperature ( $T_g$ )** It denotes the temperature below which the elastomer becomes glassy and brittle, above which it is soft and rubbery.  $T_g$  reflects molecular mobility and hence the internal viscosity of the elastomer. High  $T_g$  indicates low molecular mobility or high internal viscosity and vice versa.

**Heat build-up** The amount of heat accumulated in the elastomer when subject to cyclic deformation. It is closely related to hysteresis.

**Hysteresis** It is a term to denote energy dissipated as heat when the elastomer is subject to cyclic stresses or in a single stress-strain cycle. The area bounded by the extension and retraction curve gives a quantitative measure of hysteresis.

**Raw rubber** Fresh rubber or an elastomer as received from the supplier.

**Scorch** It is a rubber technology term to denote the occurrence of a premature crosslink, which is an undesirable feature during the shaping process.

**Vulcanize or vulcanized elastomer** Indicates rubber or elastomer that has been vulcanized or cured, and thus, contains network structure or chemical crosslinks.

**CM** Cement metal failure

**CP** Cement primer failure

**CR** Polychloroprene rubber

**CSM** Chlorosulfonated polyethylene rubber

**DCP** Dicumyl peroxide

**DOPPD** Dioctyl-*p*-phenylenediamines

**ECO** Copolymer of epichlorohydrin rubber

**ENR50** Epoxidized natural rubber (50 mol% epoxidation)

<b>λ</b>	Extension ratio
<b>ρ</b>	Density (kg m <sup>-3</sup> )
<b>χ</b>	Rubber-solvent interaction parameter

### 3.33.1 Introduction

Natural rubber and elastomers belong to the same group of materials known as high molecular weight polymers. According to the International Organization for Standardization (ISO) rubber vocabulary,<sup>1</sup> an elastomer is a macromolecular material which returns rapidly to approximately its initial dimensions and shape after substantial deformation by a weak stress

and release of the stress. However, an elastomer has always been recognized as a synthetic elastic polymer.<sup>1</sup> A polymer is a high molecular weight material having many units of small molecules chemically joined or linked by normal covalent bonds to form long chain molecules. These flexible and soft materials find wide uses in many engineering applications, such as natural rubber (NR) bridge bearings, and earthquake and seismic bearings. Indeed NR has had a sound track record in many engineering applications for over 150 years.<sup>2</sup> Elastomers have some unique properties that metals do not have. These include

- high bulk modulus (2000–3000 MPa) relative to their Young's modulus (0.5–3.0 MPa),
- some inherent damping, and
- large strain deformation.

Rubbers having high bulk modulus hardly change their volume when deformed. In simple words, rubber is incompressible. Like incompressible liquids, it has a Poisson's ratio close to 0.5. If rubber is constrained, to prevent changes in shape, it becomes much stiffer, a feature that is used to full advantage in the design of compression springs. Elastomeric bridge bearings and seismic bearings are examples of products that rely on these properties.

The damping inherent in the elastomer is a very important property as it helps to prevent the amplitude of the vibration of the spring from becoming excessive if resonant frequencies are encountered. Elastomeric products such as vibration isolators and engine mounts rely on the inherent damping properties of the elastomer.

The elastomer undergoes large strain deformation (a few hundred percent) without failure by an applied stress below its breaking stress. This means that it can store much more energy per unit volume than steel. Elastomeric dock fender systems make use of its large stored energy capacity to absorb shocks, blows and the impact exerted by ships.

Some of the merits of elastomeric springs over metal springs are as follows<sup>2</sup>:

- no maintenance is required,
- the energy storage capacity is high,
- with correct design, the rubber spring can provide different stiffness in different directions, or nonlinear load–deflection characteristics,
- a certain amount of misalignment is tolerable as the rubber spring can accommodate this tolerance,
- easier to install,
- hysteresis inherited by the elastomer is able to dampen dangerous resonant vibrations.

Another important property of an elastomer is its strong resistance to inorganic acids, salts, and alkalis. In contrast, acids attack metals. For these reasons, the linings of chemical tanks and pipes, especially those containing caustic solutions, are made from elastomers. The function of the elastomer here is to protect the metal against attack by corrosive chemicals.

Every product has its own life span. The designed lifetime of a product depends on the environmental conditions and the nature of the application. It is very important to choose the materials correctly to meet the intended service conditions and the surrounding environment. The aging process is the determining factor that limits the life span of the product. The term aging is always associated with the degradation or corrosion process as applied to metals, which may take many forms. In metals, corrosion takes place in the form of rusting, which involves oxygen and moisture. In elastomers, the term degradation is preferred to corrosion and covers a wider scope than that of metals. Degradation takes place in the form of oxidation, ozone cracking, flex cracking, liquid absorption and heat aging. Degradation in elastomers is very complex as it involves oxygen, ozone, mechanical strain, heat, trace metals, etc. There are other agencies such as solvents, oils, fuels, hot air (steam) and water, which may degrade elastomers and affect the service life of elastomeric products. A specific section on the degradation of elastomers discusses all these issues again later.

### 3.33.2 Classifications of Rubber and Elastomers

#### 3.33.2.1 Classification in Terms of Origins

Natural rubber comes from trees known as *Hevea brasiliensis*, and shrubs called guayule. The pictures in Figure 1 show typical rubber trees grown in the hot tropical climate of Malaysia, and the fresh latex that exudes from the bark of the rubber tree, after tapping with a sharp tapping knife. The fresh latex that exudes from the tree known as field latex contains about 70% water. After removing this large amount of unwanted water, the latex is known as concentrated latex and has about 60% of rubber content. Centrifuging is the preferred method of concentrating field latex because of its efficiency and rapidness compared to creaming and evaporation methods. Apart from latex, natural rubbers are available commercially in standard bale form, weighing about 33.33 kg. These bales of NR are produced specifically to meet certain

**Figure 1** Pictures of (a) natural rubber trees (top), (b) NR latex exudes from natural rubber tree (middle), and (c) closer view of NR latex collected in a cup (bottom).

technical requirements such as minimum dirt content, viscosity consistency, ash content, etc.

All synthetic elastomers are produced by the polymerization process. The early production of synthetic elastomers such as styrene butadiene rubber (SBR), polychloroprene rubber (CR), and nitrile rubber (NBR) relied on emulsion polymerization. One of the main drawbacks of emulsion polymerization is the lack of uniformity of polymer molecules with respect to stereo regularity. This is due to the

different ways in which diene monomer molecules can react, and it applies to all free radical polymerization processes of diene monomers. However, there was a real breakthrough with the discovery of the Ziegler–Natta catalyst in 1954, which enabled the control of the microstructure of polyisoprene.<sup>3</sup> Synthetic polyisoprene is produced by the solution polymerization process using catalysts of the alkyl lithium types such as trialkyl aluminum/titanium tetrachloride mixtures.<sup>3</sup> The Al/Ti mole ratio is critical for achieving high cis content. Currently, there are about 27 types of rubbers or more commercially available in the market. The choice depends on the nature of application, service conditions and environment.

### 3.33.2.2 Classification in Terms of Purposes

Elastomers can be classified further either as general-purpose rubbers or as specialty rubbers. General-purpose rubbers are those elastomers that are widely used in the manufacture of tires, industrial rubber goods (IRG), and general rubber goods (GRG). Most of the general-purpose elastomers cannot meet high service temperature and high oil resistance specifications or the combinations of these two requirements. The most common general-purpose rubbers include NR, SBR, CR, NBR, ethylene–propylene–diene rubber (EPDM), and BR. In contrast, specialty rubbers are those elastomers that are tailor made to meet certain specific requirements, such as low temperature flexibility, high swelling resistance towards oil (hydrocarbon, fuel, gasoline, etc.) and very high service temperature or combinations of these requirements. Specialty rubbers include silicone rubber, fluoroleastomers, epichlorohydrin, chlorosulfonated rubber, etc. [Table 1](#) shows some of the rubbers which belong to these grades and their typical applications.

### 3.33.2.3 Classification in Accordance with International Organization for Standardization

Elastomers can also be classified according to the ISO 4632/1-1982(E)<sup>4</sup> which provides information about rubber as a material with specifications. They are classified and designated in terms of their performance to heat aging, swelling resistance towards oil and low temperature flexibility. This method of classification is very helpful as it facilitates the purchasers and suppliers to make the correct selection of suitable materials, and avoid wasting time and energy.

These designations are determined by a type based on resistance to heat aging, by a class based on resistance to swelling in oil, and by a group based on low temperature resistance.<sup>4</sup> These classification criteria are used to establish a characteristic material designation consisting of three capital letters, where

- the first letter signifies Type (heat resistance)
- the second letter signifies Class (oil resistance)
- the third letter signifies Group (low temperature resistance).

[Tables 2–4](#) show the heat aging temperature, limits of volume swell and brittleness temperature for establishing Type, Class and Group respectively.<sup>4</sup> Type is determined by the maximum temperature at which heat (air oven) aging for 70 h, in accordance with ISO 188, causes a change in tensile strength of not more than  $\pm 30\%$ , a change in elongation at break of not more than  $-50\%$ , and a change in hardness of not more than  $\pm 15$  International Rubber Hardness Degrees (IHRD). Class is based on the resistance of the material to swelling in American Society for Testing Materials (ASTM) Oil No. 3, when tested in accordance with ISO 1817. In the test, the immersion time shall be 70 h at a temperature determined in [Table 2](#). Group is based on the brittleness temperature of the material when measured in accordance with ISO/R 812.

Thus if an elastomer is designated as BCD, it means that it is classified as Type B, Class C and Group D. This implies that the elastomer resists temperatures up to  $100^{\circ}\text{C}$ , with volume swelling not exceeding  $120\%$  in oil No. 3 and is not brittle at  $-40^{\circ}\text{C}$ .

Most of the general purpose elastomers shown in [Table 1](#) have poor heat resistance except for ethylene propylene rubber (EPM) as shown in [Figure 2](#). EPM can withstand service temperature of about  $150^{\circ}\text{C}$  as it is categorized as Type D. General purpose elastomers also have poor swelling resistance towards hydrocarbon oil except nitrile rubber (NBR) which is classified as Class H with maximum volume swell of  $30\%$ . A majority of the specialty elastomers shown in [Table 1](#) have both excellent heat resistance and swelling resistance. From the chart shown in [Figure 2](#), silicone rubber having both methyl and vinyl substituent groups on the polymer chain (VMQ) has equivalent heat resistant (Type G) with silicone rubber having methyl, vinyl, and fluorine substituent groups on the polymer chain (FVMQ). However, they have different Class with respect to swelling resistance. VMQ belongs to Class E while FVMQ belongs to Class J. Clearly

**Table 1** General purpose rubbers and specialty rubbers

<i>General purpose rubbers</i>	<i>Typical applications</i>	<i>Specialty rubbers</i>	<i>Typical applications</i>
Natural rubber (NR)	Mainly for tires, industrial and general rubber goods, bridge and earthquake bearings, bridge expansion joints, etc.	Carboxylated nitrile rubber (XNBR)	Oil resistant hoses, boots, seals and gaskets and other automotive components with very good oxidation resistance
Synthetic polyisoprene (IR)	Tires, sports goods, earthquake rubber bearings, IRG.	Polysulphide rubber (PTR)	Used mainly where good resistance to solvents is required
Styrene butadiene rubber (SBR)	Passenger car tires, IRG, GRG	Polyurethane rubber (AU, EU)	Gaskets, seals, solid tires, and foams
Butyl rubber (IIR)	Tire tubes, tube liners, enclosures, air bags, and curing bladders	Silicone rubber (Si)	Able to withstand a very wide range of service temperatures from $-45$ to $200^{\circ}\text{C}$ . Various grades are available covering a very wide range of applications such as baby teats, catheters, medical applications, wire and cables, electronic components, etc.
Butadiene rubber (BR)	Tires, sports goods	Chlorosulfonated polyethylene rubber (CSM)	Electrical insulator in cable and wire industry, tank lining, colored-stable weather-resistance products, oil resistant hoses and gaskets
Ethylene-propylene-diene rubber (EPDM)	Gaskets, seals, automotive components, IRG, and GRG	Polyacrylic rubber (ACM)	Seals and gaskets for high temperature applications, $180$ – $200^{\circ}\text{C}$
Polychloroprene rubber (CR)	Hoses, rubber bearings, expansion joints, belts, and conveyors	Fluorocarbon rubber (FPM)	Products which are resistant to chemicals, oils and solvents. Able to withstand high service temperatures exceeding $250^{\circ}\text{C}$ . Outstanding oxidation and ozone resistance. Flame resistant. Hoses, gaskets and seals for aircraft, jets, and rockets
Nitrile rubber (NBR)	Oil-resistant hoses, seals, O-rings, gaskets	Epichlorohydrin rubber (ECO)	Automotive industry – gasket, seals, hoses to withstand service temperatures above $130^{\circ}\text{C}$

**Table 2** Heat aging temperature for establishing Type<sup>4</sup>

	<i>Type</i>									
	A	B	C	D	E	F	G	H	J	K

Limiting brittleness temperature (°C)	0	−10	−25	−40	−55	−75	−85

**Figure 2** A chart showing type and class of elastomers. Adapted from Hashimoto, K.; Maeda, A.; Hosoya, K.; Todani, Y. *Rubb. Chem. Technol.* **1998**, 70(3), 449–519, with permission from American Chemical Society.

FVMQ is more resistant to swelling towards the solvent than VMQ grade, as the fluorine atom is highly polar. **Figure 3** shows the general chemical structure of silicone rubber with different substituent groups.

The main backbone chain is made of repeating  $-\text{Si}-\text{O}-$  groups while the methyl groups are attached at the side. Both  $\text{Si}-\text{O}$  and  $\text{Si}-\text{CH}_3$  bonds are thermally stable. This explains why VMQ and FVMQ grades have the same Type of heat resistance, as the main chain backbone is the same for both. The  $\text{Si}-\text{O}$  bond is partially ionic and it is relatively easy to be broken by concentrated acids and alkalis even at room temperature. Another important feature of the chemical structure of silicone rubber is the relatively large bond angle of  $\text{Si}-\text{O}$  (about  $140^\circ$ – $160^\circ$ ).<sup>7</sup> The intermolecular forces between silicone chains are very low probably because of the large distance between the adjacent chains, as silicone atoms are relatively large. Thus this facilitates ease of chain rotation which accounts for the lowest glass-transition temperature  $T_g$  ( $\sim -120^\circ\text{C}$ ) among the commercially available elastomers. The dimethyl rubbers swell more in aliphatic and aromatic hydrocarbons than in acetone and diesters. However, the swelling resistance towards hydrocarbon oil can be enhanced by the replacement of one methyl group on each silicon atom by a more polar group such as trifluoropropyl group ( $-\text{CH}_2\text{CH}_2\text{CF}_3$ ), that is, the FVMQ grade.

### 3.33.3 General Properties of Elastomers

All elastomers have some common properties such as being flexible, tough, relatively impermeable to both water and air, and elastic when vulcanized. One of the unique features of a vulcanized elastomer is its ability to exhibit high elasticity: the elastomer can be stretched to a few hundred percent and recover its original shape and dimensions almost instantaneously when the deforming force is released. For a material to exhibit high elasticity, it must fulfill the following conditions:

- flexible long chain molecules with relatively low molecular interaction forces,
- the long chain molecules must be cross linked (at least 2% cross linked network),
- rubbery above  $T_g$

The elasticity of an ordinary solid such as metal is associated with its internal energy. In contrast, the elasticity of rubber is entropy driven.

Elastomers are also well known for their good resistance to acids, alkali and chemical solutions. Elastomers have a proven record of accomplishment as the material used for tank lining or related chemical vessels. Beyond these common characteristics, each rubber has its own unique properties depending on the chemical structure as discussed briefly below.

#### 3.33.3.1 Structure–Property Relationship

The effects of chemical structure on some important physical and technological properties are summarized in **Table 5**.

##### 3.33.3.1.1 Mechanical strength

Tensile strength, tear strength, crack-growth resistance and fatigue life of the vulcanized elastomer depend on the chemical structure and its geometrical configurations. Elastomers having regular microstructure are able to crystallize, and those that have irregular microstructure are amorphous. **Figure 4** shows the chemical structure of general-purpose elastomers such

**Figure 3** Chemical structure of silicone rubber: MQ grade consists of methyl, PMQ grade consists of benzene rings and VMQ grade consists of vinyl.

**Table 5** Influence of chemical structure on physical and technological properties of elastomers

Basic structure	Technological significance
1. Nature of carbon-carbon backbone chain (i) Double bonds (ii) Single bonds	Unsaturated elastomers (having double bonds) are capable of being vulcanized with sulfur. Saturated elastomers (having single bonds) cannot be vulcanized with sulfur, but with peroxide. Unsaturated elastomers have poorer ozone cracking resistance and poorer oxidative resistance than saturated elastomers
2. Geometrical configurations	Regular microstructure would favor crystallization. Irregular microstructure leads to amorphous elastomers. The degree of crystallization affects mechanical strength
3. Polarity	Affects the degree of swelling resistance, rubber to metal bond strength, $T_g$ and electrical resistivity
4. Chain flexibility and glass transition temperature, $T_g$	Affects hysteresis and damping, and other related properties such as resilience, heat build-up, mechanical strengths, etc.
5. Molecular weight distribution	Broad molecular weight distribution provides easier processing than narrow molecular weight distribution

as natural rubber (NR), styrene butadiene rubber (SBR) and polychloroprene rubber (CR).

Natural rubber is 100% *cis*-1,4-polyisoprene indicating that it has regular microstructure, thus enabling it to crystallize. NR will crystallize at low temperatures. Crystallization has its own kinetic; in the case of NR the maximum rate of crystallization occurs at  $-26^\circ\text{C}$ .<sup>2,6</sup> When the rubber crystallizes, it hardens progressively and eventually loses its flexibility and rubber-like elasticity. The maximum amount of crystalline region is about 33% in the case of NR. However, if a tensile strain (more than 200%) is applied to NR it crystallizes almost instantaneously even at high temperatures. This phenomenon is known as strain-induced crystallization. Since crystallization is a reversible process, the crystals are completely melted once the applied strain is removed.

Low temperature crystallization brings few disadvantages to NR, particularly when it involves mixing. When NR crystallizes, it becomes very stiff and may cause damage to the mills. To overcome this problem, the common practice is to place the crystallized NR in a hot room (oven) to melt the crystals so that the rubber regains its flexibility. Any unmelted crystals

present during the mixing process would interfere with the incorporation and dispersion of the compounding ingredients. In contrast, strain-induced crystallization offers a big advantage in that it helps to enhance the mechanical strength of the rubber. For example, an unfilled or gum NR vulcanizate gives higher tensile strength (23–27 MPa) than unfilled SBR gum vulcanizate (2–3 MPa). Unfilled (gum) vulcanizate refers to a vulcanized rubber containing no filler apart from the compounding ingredients necessary for vulcanization. The crystals that are formed during straining act like a reinforcing filler to enhance the tensile strength. Thus for a noncrystallizing elastomer, it is necessary to incorporate a reinforcing filler into the rubber to enhance its strength.

In addition to the reinforcing filler, the types of chemical crosslink such as polysulfidic (C–S<sub>x</sub>–C), monosulfidic (C–S–C), or carbon-carbon (C–C) also affect the strength of the vulcanized elastomer.<sup>8</sup> Polysulfidic crosslinks are weak and labile with lower bond energy than monosulfidic and carbon-carbon links. Polysulfidic crosslinks enhance mechanical strengths such as tensile and tear strengths because these weak and labile crosslinks relieve stresses by ‘yielding.’<sup>8</sup>

**Figure 4** Chemical structure of general-purpose elastomers.

Besides NR, polychloroprene rubber (CR) can also crystallize. Indeed CR crystallizes more readily than NR does because trans 1,4 configuration allows better molecular packing than cis 1,4 configuration.

### 3.33.3.1.2 Oxidation and ozone resistance

All unsaturated elastomers are susceptible to attack by oxygen and ozone which ultimately leads to chain scission followed by progressive loss in the physical properties. This aspect of oxidation will be discussed further in a later section. Almost all specialty elastomers have saturated bonds on the main backbone as well as high bond dissociation energy. Thus, specialty elastomers are highly resistance to heat, oxidation and ozone cracking.

### 3.33.3.1.3 Swelling resistance

The swelling resistance of rubber towards hydrocarbon oil depends on the extent of the polarity of the elastomer. The more the polar groups attached to the rubber molecules the higher is the polarity, and

the better is the swelling resistance towards hydrocarbon oil. The solubility parameter of elastomers and liquids determines the extent of compatibility and swelling resistance. The closer the solubility parameters between the elastomer and the liquid, the better is their compatibility. Indeed, the greater the thermodynamic compatibility between liquid and elastomer, the greater the absorption of liquid occurring when both have similar solubility parameters. The solubility parameter  $\delta$  is related to a parameter to measure the specific interaction between molecules known as cohesive energy density (CED) by the following mathematical relationship.

$$\delta = (\text{CED})^{1/2} \quad [1]$$

$$\text{CED} = (\Delta H - RT)/(M/\rho) \quad [2]$$

where  $\Delta H$  is the latent heat of vaporization,  $T$  is the absolute temperature,  $M$  is the molecular weight of the polymer,  $\rho$  is the density of the polymer, and  $R$  is the molar gas constant. For example, natural rubber has a solubility parameter value of 16.7 and NBR has

a solubility parameter between 21.0 and 22.0 MPa<sup>1/2</sup>. Most of the petroleum oils have a solubility parameter of 16.3 MPa<sup>1/2</sup>. Thus NR will swell markedly in petroleum oil because their solubility parameters are similar. In contrast, NBR has a solubility parameter very much higher than that of petroleum oil, so the two are not compatible. For this reason, polar NBR shows higher swelling resistance than nonpolar NR towards petroleum oil. Elastomers with higher polarity such as polyurethane rubber (AU) show even higher swelling resistance to nonpolar solvents than nonpolar elastomers. Based on the solubility parameter, polar rubbers swell more in polar solvents. Nonpolar rubbers are resistant to swelling in polar solvents.

#### 3.33.3.1.4 Glass-transition temperature $T_g$

The glass-transition temperature ( $T_g$ ) is the temperature at which molecular mobility begins to take place, below which molecular mobility is frozen and the elastomer becomes rigid and glassy. The  $T_g$  of the elastomer depends on the chemical structure of the elastomer. The presence of a polar atom, side groups, length of side chains, and crosslink reduces molecular mobility which would increase  $T_g$  of the elastomer. The glass-transition temperature affects a number of important technological properties such as strength, damping, low temperature flexibility, rolling resistance, wet grip, etc. High  $T_g$  elastomers are preferred to low  $T_g$  elastomers for applications where high mechanical strength, high damping, and excellent wet traction are required. For applications where excellent low temperature flexibility, low heat

generation, high resilience and low rolling resistance are required, low  $T_g$  elastomers are preferred to high  $T_g$  elastomers.

**Table 6** summarizes the respective  $T_g$ , ozone cracking resistance, chemical resistance and heat aging resistance of some of the important commercial elastomers.

### 3.33.4 Rubber Technology and Compounding

#### 3.33.4.1 Mastication and Mixing

Rubbers find very limited applications in their raw form. In their raw form, rubbers may be suitably used as binders and adhesives because of their inherent tack. To become useful products, they have to undergo various processes from mastication, mixing, shaping or fabrication prior to molding, as shown by the schematic flow chart in **Figure 5**.

#### 3.33.4.2 Rubber Compounding

Rubber compounding is the term used to denote the art and science of selecting and combining elastomers and additives to obtain an intimate mixture that will develop the necessary physical and chemical properties for a finished product. In compounding, one must cope with literally hundreds of variables in materials and equipment. There are three main areas of concern in rubber compounding, namely, (i) to secure certain properties in the finished product to

**Table 6** Some important technological properties of some important commercial elastomers

Elastomer	$T_g$ (°C)	O <sub>3</sub> resistance	Swelling resistance (%) <sup>a</sup>	Heat resistant up to (°C) <sup>b</sup>

satisfy service performance; (ii) to be able to meet processing characteristics for efficient utilization of available equipment, and (iii) to meet conditions (i) and (ii) at the lowest possible cost. In other words, the most important criteria in compounding are to secure an acceptable balance among demands arising from the three concerned areas.

Theoretically, a rubber compound may consist of an elastomer and a cross linking agent. However, in practice, a rubber compound may contain 5 ingredients or even more than 10 ingredients, depending on the intended products, types of application and their service conditions. Each ingredient has a specific role and function(s). Each has an impact on properties, processability, and price. The real challenge is to develop a high quality rubber product at the lowest cost possible. The materials utilized by the rubber compounder can be classified into nine major categories, which are defined as follows:

- **Elastomers:** The basic component of all rubber compounds may be in the form of rubber alone, or master batches of rubber–oil, rubber–carbon black, or rubber–oil–carbon black.
- **Vulcanization agents:** These materials are necessary for vulcanization processes where chemical crosslinks are introduced into the rubber matrix to form a three-dimensional network. Crosslinks inhibit permanent flow under deformation or heat and prevent dissolution in solvents. Strength, stiffness and resilience increase upon cross linking, and set, stress-relaxation and creep decrease.
- **Accelerators:** In combination with vulcanizing agents, these materials reduce the vulcanization time (cure time) by increasing the rate of vulcanization. In most

cases, the physical properties of the products are also improved.

- **Activators:** These ingredients form chemical complexes with accelerators, and thus aid in obtaining the maximum benefit from an acceleration system by increasing vulcanization rates and improving the final properties of the products.
- **Age-resistors:** Antioxidants, antiozonants, and other materials are used to slow down ageing processes in the vulcanizates.
- **Fillers:** These materials are used to reinforce or modify physical properties, impart certain processing properties, and reduce cost.
- **Processing additives:** Formerly known as processing aids, the new term currently used is processing additives. These are materials used to modify rubber during the mixing or processing steps, or to aid in a specific manner during extrusion, calendering, or molding operations.
- **Softeners:** They are materials that can be added to rubber either to aid mixing, produce tack, or extend a portion of the rubber hydrocarbon (e.g., oil extended).
- **Miscellaneous ingredients:** These materials can be used for specific purposes but are not normally required in the majority of rubber compounds. They include retarders, colors, blowing agents, abrasives, dusting agents, odorants, etc.

### 3.33.4.3 Vulcanization

Vulcanization is a process of cross-linking rubber molecules chemically with organic/inorganic substance through the action of heat and pressure. The

rubber which is cross linked chemically is known as vulcanizate. The introduction of crosslinks into the rubber matrix may be comparatively few in number but are sufficient to prevent unrestricted flow of the whole molecules past neighboring ones. The low concentration of crosslinks implies that the vast majority of the segments making up the long chain molecules are free to move by virtue of kinetic energy. An unvulcanized rubber dissolves completely in its solvent. In contrast, a vulcanized rubber only swells. The chemical crosslinks prevent complete dissolution. A vulcanized rubber in this sense is a solid and will retain its shape and dimensions.

Vulcanization is a very important process in the rubber industry and conducted at relatively high temperatures (140–200 °C). For latex dipped goods, vulcanization is conducted at relatively low temperatures (60–120 °C) and requires no pressure as the latex is in fluid form and flows to take the final shape of the former and mold.

One of the most important chemicals in vulcanization is the cross linking agent. Elemental sulfur is the most widely used cross linking agent in the rubber industry because it is very cheap, abundant and easily available. Besides, sulfur is very easy to mix and readily soluble in the rubber. By varying the amount of sulfur to the accelerator ratio one can get different types of crosslink in the rubber matrix. Table 7 summarizes the types of sulfur vulcanization system,<sup>10</sup> nature of crosslinks produced and their influence on technological properties. Thus sulfur vulcanization provides flexibility as one can control the type of crosslink intended for specific use or applications. The most basic requirement for sulfur vulcanization is the availability of double bonds on the rubber hydrocarbon. The nonsulfur cross-linking agents include organic peroxides, quinines and their oximes and imines, metallic oxides and high energy radiation. The detailed mechanisms of vulcanization with these vulcanizing agents are discussed by Elliot and Tidd.<sup>10</sup>

There is another type of sulfur vulcanization system known as soluble efficient vulcanization (EV)<sup>10</sup> intended for engineering products that require consistent stiffness, low creep, low stress-relaxation and low set. This vulcanization system employs certain soluble accelerators, activators, and sulfur that completely dissolve in rubber giving a truly homogeneous compound.<sup>10</sup> In practice, this is achieved by selecting accelerators and activators that have a fairly high solubility in rubber at room temperature. Suitable accelerators for soluble EV include diphenyl guanidine, tetrabutylthiuram disulphide and *N*-oxydiethylenebenzothiazole-2-sulphenamide. Zinc oxide is insoluble in rubber, but it has to be included in the system as it plays a major role in sulfur vulcanization. However, 2-ethyl hexanoic replaces the common coactivator stearic acid as the latter reacts with zinc to form an insoluble zinc stearate which induces creep and the former forms a rubber-soluble zinc salt. The sulfur dosage employed in soluble EV must not exceed 0.8 pphr (parts per hundred of rubber) to ensure that it remains dissolved in the rubber and with no tendency to bloom to the rubber surface.

Nonsulfur vulcanization such as the peroxide vulcanization system produces carbon-carbon type of crosslink that gives excellent heat aging resistance and very low compression set. However, the mechanical strengths are lower than polysulfidic and monosulfidic crosslinks. The choice of vulcanization system depends on the service environment as well as the mode of deformation for the intended rubber product.

### 3.33.5 Rubber-to-Metal Bonding – Engineering and Automotive Applications

Most of the rubber springs involve bonding of rubber to metal. In many cases the metal parts are required for fixing purposes, particularly those of automotive components such as rubber bushes, engine mounts

**Table 7** Sulfur vulcanization systems, types of crosslink produced and their effect on technological properties

<i>Vulcanization system</i>	<i>Sulfur</i>	<i>Accelerator</i>	<i>Type of crosslink</i>	<i>Technological properties</i>
Conventional	2.0–3.5	1.0–0.4	Polysulfidic	Increase tensile and tear strengths, high compression set, and poor heat aging
Efficient (EV)	0.3–0.8	6.0–2.5	Monosulfidic	Excellent heat aging, low compression set, low tensile, and tear strengths
Semi-EV	1.0–1.7	2.5–1.0	Mixtures of poly, di- and mono	Compromise or balance in terms of strength and heat aging

and couplings. **Figure 6** shows some typical rubber-to-metal bonded products. In tank lining, the main function of rubber is to protect the metal against attack by corrosive chemicals as well as to protect the metal parts from oxidation by air and moisture, which leads to rusting.

The laminated rubber bearing consists of alternate layers of metal plates. The metal plates serve to restrain the lateral expansion of the rubber on compression. Because of restriction at the rubber metal interface, due to friction or when the rubber is bonded to metal, the rubber bulges at the end plates to maintain a constant volume. As a result, the effective compression modulus is dependent on the shape factor,  $S$ , defined as the ratio of loaded area to force free area.<sup>2</sup>

$$S = \text{Loaded area/Force free area} \quad [3]$$

For a rectangular rubber block of length  $L$ , width  $W$  and thickness  $h$ , shape factor  $S$  is given by eqn [4]:

$$S = LW/[2b(L + W)] \quad [4]$$

The dependence of the compression modulus on the shape factor has a significant advantage where the vertical stiffness increases substantially, by inserting horizontal metal spacer plates into the rubber. For a rectangular rubber block having length  $L$ , width  $W$  and height  $h$ , the shear stiffness and compression stiffness are given by eqns [5] and [6] respectively.

$$k_s = GA/b \quad [5]$$

$$k_c = 3G(1 + 2S^2)A/b \quad [6]$$

Here,  $G$  is the shear modulus of the vulcanizate and  $A$  is the cross-sectional area of the rubber surface subjected to shear or compression. Equation [6] shows

Rubber bearing

**Figure 6** Rubber-to-metal bonding products – (a) tank lining (LHS), (b) various automotive rubber products (RHS) and (c) below rubber bridge bearing.

that the compression stiffness can be increased substantially by increasing the shape factor. The shape factor does not affect shear stiffness. For these reasons, laminated steel rubber bearings are used in bridges, where high compression stiffness is necessary to support all dead and live loads of the deck, and very low shear stiffness to accommodate movements associated with thermal expansion and contraction due to temperature changes.

To achieve efficient bonding at the rubber–metal interface, it is necessary that the rubber is chemically bonded to the metal surface. This is achieved in practice by following proper procedures laid down in the following section.

### **3.33.5.1 Bonding of Rubber to Metal**

#### **3.33.5.1.1 Preparation of metal plates**

The metal plates must be clean and free from any contamination such as oil, grease, protective coating, and rust. Exposing the contaminated metal surface to the vapor of a suitable organic solvent (e.g., chlorinated solvent) removes oil and grease. The next step is to remove metal oxides and rust on the metal surface, usually by the sandblasting technique or wire brushing. Apart from cleaning, sandblasting increases the surface area, which is very beneficial for strengthening the bonded area. Acid etching provides an alternative means of removing metal oxides from the metal surface.

It is very vital that the metal surface is completely free from oil, grease and rust to ensure efficient wetting of the bonding agent on the metal surface so that during vulcanization the bond formed between rubber and metal via the bonding agent is very strong. However, a few precautions need to be observed when sandblasting on the metal surface. The grit size, gun pressure and shooting distance must be correct to get the right surface topology, thus avoiding excessive wear or too little wear.

#### **3.33.5.1.2 Types of bonding agent and methods of applications of bonding agent to metal plates**

The common bonding agents for bonding rubbers to metals include ebonite solution or sheet, brass and proprietary adhesives. In the past, the bonding agent as well as the lining material for making tank lining was ebonite solution and calendered ebonite sheet. The ebonite compound contains a high amount of sulfur, about 25–35 pphr. This high sulfur content makes ebonite a hard and brittle material. Indeed ebonite is a thermoset as it is highly cross linked.

The high sulfur content of ebonite introduces high polarity that makes it a very suitable bonding agent. Despite the superior chemical resistance of ebonite, there are a few limitations such as its brittleness after cure, long cure time and potential of fire hazard due to exothermic reaction during curing, especially when a thicker lining is involved. For this reason, soft rubber linings are preferred to ebonite linings.

Brass is a very good bonding agent, and is widely used in the tire industry. Brass is coated on steel wire cords by the electroplating process. Brass-coated steel wire cords are used as breakers or belts placed underneath the tread and on top of the carcass of the green tire. During vulcanization, the sulfur forms covalent bonds with both the rubber and the component metals of the brass, leading to a very strong bond.<sup>11</sup>

In most rubber-to-metal bonded products, a proprietary bonding agent is preferred to the other two bonding agents. A proprietary bonding agent usually requires two coatings, *viz.* a primer and an adhesive cement. There are reasons why a two-coat system offers more insurance for the rubber to metal bond. The first coating known as a primer helps to eliminate corrosion in corrosion-prone metals when they are in contact with the rubber.<sup>12</sup> By using a primer, secondary cement (second coating–adhesive) that has a greater degree of bondability to the stock being used can be selected, rather than a one-coat system.<sup>12</sup> It is claimed that the two-coat system allows more metal adhesion into the primer, and more stock adhesion into the cement coat.<sup>12</sup> This results in a higher intrinsic bond with the two-coat system than a single coat system.

Bonding agents are applied by painting, spraying or dipping on treated metal parts in the form of a solution or aqueous suspension.

#### **3.33.5.1.3 Molding of rubber-to-metal bonded parts**

Finally, the dried, coated metal parts are loaded into the mold and the rubber is vulcanized in contact with these substrates by the conventional rubber molding techniques such as compression, transfer and injection molding. It is during this vulcanization process that the rubber is chemically bonded to the metal surface when the cross linking agents react with the adhesive.

However, in the case of tank lining, the method is different from the conventional rubber-to-metal bonded products. The method of applying calendered rubber sheeting onto the prepared metal surfaces is

analogous to that of applying rolls of wallpaper to the walls of a room. However, care must be taken to avoid entrapment of air between rubber and metal. The rubber sheet is laid down at the correct angle, and is rolled down into close contact with the adhesive. Applying the rubber sheet at the corner or edges of the tank is quite tricky. In practice, this is achieved by making joints at corners by inserting and rolling down an extruded rubber fillet of triangular cross-section and forming the sheet joints on top of the fillet. This technique gives to the lining a well finished appearance and reduces the danger of weak joints occurring in corners.

Upon completion of laying the rubber sheet onto the metal surface, the covered lining tank is usually allowed to rest for at least 24 h before being vulcanized. This resting period allows any air trapped between rubber and metal to diffuse, apart from enabling the adhered rubber sheet to recover and settle down before it is heated.

### 3.33.5.2 Vulcanization

It is usually done in an open steam autoclave for tanks or vessels that are small enough to go into the autoclave. When the lined vessel is too large to be accommodated in an autoclave it may be vulcanized in one of the following methods:

#### 3.33.5.2.1 Low or high pressure steam

This method is applicable to a vessel that has sufficient strength to withstand internally applied pressure. This procedure can be adopted if the vessel such as road or rail tank cars can be lined and then sealed and bolted to give a strong and steam proof pressure container. The steam pressure is passed through the lined vessel to the desired vulcanization temperature until the rubber is fully vulcanized. There are some elements of danger when dealing with high pressure steam. So it is very important that all the safety regulations are met in terms of design and material of the vessel. The work should be done under skilled engineering supervision.

#### 3.33.5.2.2 Water curing technique

This method is suitable for tanks or vessels that are too weak structurally to be put under steam pressure. Here, the lined tank is filled with water or brine. The water is heated by passing live steam into the water until it approaches boiling point. This temperature is maintained for a few hours until the rubber is fully vulcanized. Care must be taken to ensure that live steam does not impinge on the rubber lining to

avoid the occurrence of a large blister between the rubber and metal at the point of impingement. It is necessary to conserve heat by shielding the unit against draughts and cold to minimize temperature variations which would affect the uniformity of the cure.

#### 3.33.5.2.3 Hot air or ambient temperature vulcanization

This method is suitable for tanks or vessels which do not work with the methods discussed above. The choice of accelerator is very important. Ultrafast or very fast accelerator is usually used in the rubber compound. Care has to be taken to ensure that the rubber does not vulcanize prematurely (scorched) before it is applied onto the treated metal surface. One of the means to overcome the problem is to avoid mixing the accelerator and sulfur together, but to prepare sulfur masterbatch and accelerator masterbatch separately. The two masterbatches are blended together just prior to calendering, and the calendered sheet applied as soon as possible to the metal to avoid the risk of being scorched.

### 3.33.5.3 Types of Bond Failure and Possible Remedies

A rubber shear mount may be expected to deform up to 300% shear strain, and the mean shear stress acting on the rubber-to-metal bond can be as high as 10 MPa or 2/3 tons per square inch.<sup>11</sup> Steel laminated rubber bearings for bridges must have a minimum bond strength of about 9 N mm<sup>-1</sup> (MS 671, 1991).

It is important to observe the failure mode that occurs in rubber-to-metal bonded products because it throws some light and clues to the root cause of the problem. It is usual to conduct peel test to determine the interfacial bond strength between the rubber and metal. There are two basic types of bond failure either adhesive or cohesive. Adhesive failure may occur at the interfacial between the rubber and substrate, or between cement and substrate. Cohesive failure occurs within the rubber itself. There are three modes of adhesive failure.<sup>13</sup> First is called CM failure that takes place between primer and metal interface. Second is CP failure that occurs at the primer to cover cement interfacial. Third is RC failure where the bond fails at the rubber-cover cement interface. RC failures are the most common and the most difficult to solve.<sup>13</sup> There are a number of causes, which bring about these bond failures. They include the following: metal surface not cleaned efficiently due to poor cleaning procedure,

contamination of metal surface during handling, incomplete wetting of adhesive on the metal surface, variations of temperature of metal surface, precured adhesive, sweeping of adhesive during molding etc.<sup>13</sup> There are remedies to overcome these problems. First, ensure that the metal surface is free from all forms of contamination. Second, avoid contamination of metal surface during handling. Third, apply the primer and adhesive cement onto the metal surface evenly by taking care of the correct viscosity of the adhesive, and correct spraying distance and thickness of the adhesive film. Fourth, use the correct type of adhesive and follow strictly the instruction and procedure recommended by the chemical supplier.

If during the peel test, cohesive failure occurs within the bulk of the rubber, then this indicates that the interfacial bond strength between the rubber and metal plate via the bonding agent is stronger than the cohesive strength of the rubber itself.

### 3.33.6 Oxidation of Rubber

Metals oxidize in the presence of air and water and consequently they corrode, become rusty and weak. **Figure 7** shows the old version of using steel rollers to accommodate movements of the bridge deck brought about by expansion and contraction due to temperature changes.<sup>14</sup> The steel rollers corroded and suffered high wear and tear. In contrast, laminated steel rubber bearing did not show any sign of wear out after nearly twenty years of installation.<sup>14</sup> However, this does not mean that elastomeric bearing will last forever. Like metals, rubbers are also prone to corrosion. Corrosion of rubbers is associated with the aging process known as degradation. All unsaturated rubbers are subject to degradation due to the attack of heat, ultraviolet (UV) light, oxygen,

ozone etc. The more is the amount of unsaturation the more it is susceptible to degradation. The term aging as applied to rubber, covers a variety of phenomenon arising out of the factors described above. Aging properties of raw rubber differ from vulcanized rubber because of the latter's specific network structure and extra network material. When natural rubber is heat-aged in the presence of oxygen or air, it invariably loses strength, in particular its tensile strength decreases. The pattern of modulus change during aging is not so straight forward because there are two opposing reactions which can occur simultaneously. One is degradation of the molecular chains and crosslinks which causes softening; the other is additional cross linking which causes stiffening. Under any given set of aging conditions (time and temperature) either softening or stiffening reactions may predominate depending on the type of vulcanization system, type of filler and antidegradants employed in the rubber compound.

Oxygen reacts with rubber only after the rubber has been acted upon by energy. This is usually from UV light, heat or mechanical energy (flexing). This energy dislodges a hydrogen atom from the rubber molecule, resulting in the formation of a radical. The oxidation of polymer with elemental oxygen is called autoxidation because it is an autocatalytic. The rate of autoxidation is affected by temperature, the presence of catalyst and also the presence of antioxidant. When the oxygen attacks the rubber it produces hydroperoxide. The hydroperoxides break to form free radicals. This is an autocatalytic, self generated free radical process. The autoxidation process involves three main stages, namely, initiation, propagation and termination. In view of the complexity of autoxidation reaction with rubber, Bolland and Gee<sup>15,16</sup> used model olefins to study the kinetics of autoxidation. **Figure 8** shows the mechanism of autoxidation as proposed by Bolland.<sup>15,16</sup>

**Figure 7** (a) Steel roller bridge bearing and (b) steel laminated rubber bearing installed in 1955. Adapted from Mullins, L. *Proc. Rubb. in Eng. Conf.* Kuala Lumpur, 1974, pp. 1–20, with permission from the Malaysian Rubber Board.

**Figure 8** Mechanism of autoxidation of natural rubber as outlined by Bolland. Adapted from Barnard, D.; Lewis, P. M. In *Natural Rubber Science and Technology*; Robert, A. D., Ed. Oxford University Press, 1988; Chapter 13, pp 621–673, with permission from . . .

The autoxidation is initiated with the generation of free radicals due to the relatively facile homolysis of traces of peroxide present in the elastomer.<sup>17</sup> The rate of oxidation is related to the concentration of the hydroperoxide [ROOH] as shown by eqn [I] below<sup>16</sup>.

$$r_i = k_i[\text{ROOH}]^2 \quad [\text{I}]$$

The resultant free radicals react with oxygen to form the deleterious peroxides and propagate the autoxidation reaction. The rate of propagation is controlled by the hydroperoxide yields and those of decomposing. The hydroperoxide yields for a large number of olefins range from almost 100% downwards to values controlled by side reactions of the peroxy radicals, such as addition to olefinic double bonds, when hydrogen abstraction becomes relatively difficult.<sup>16</sup> Such side reactions would continue the propagation chain. However, when the value of the rate constant  $k_2$  becomes large, the reaction of alkenyl radicals with oxygen become independent of oxygen pressure. Under these conditions, rate-determining step is no longer controlled by the rate constant  $k_3$ , of the hydrogen abstraction step. Termination would occur primarily by the interaction of alkenyl radicals. Then the propagation rate is given by eqn [II] below<sup>16</sup>.

$$r = r_i^{1/2} k_2 k_4^{-1/2} [\text{O}_2] \quad [\text{II}]$$

Termination occurs solely by the mutual destruction of peroxy radicals and represented by the following rate equation<sup>16</sup>:

$$r = r_i^{1/2} k_3 k_6^{-1/2} [\text{RH}] \quad [\text{III}]$$

The outcome of this autoxidation is either chain-scission or cross-linking. If chain-scission occurs, the degraded rubber will be soft and tacky. On the other hand, if cross linking occurs the degraded rubber will be hard and brittle. In both cases, the mechanical strength of the rubber decreases markedly. Model olefins were used to study the mechanism of oxidation of NR due to complexity of the oxidation reaction in particular when the rubber is vulcanized.<sup>16</sup> The oxidation of rubber vulcanizate is technologically important since the absorption of only a small amount of oxygen (1%) by rubber vulcanizate results in a considerable change in the physical properties.

It is believed that the oxidation of natural rubber follows the same route and analogous to that of the model olefins where the polyisoprene chain undergoes scission.<sup>16</sup> An essential concept of this process is the number of molecules of oxygen absorbed per scission event. According to Bolland,<sup>15</sup> the oxidation reaction would finally lead to an alkoxy radical disproportionate to butan-2-one-4-al rather levulinaldehyde, and the vinylic radical would have to be oxidized further to the methyl ketone end group. Minute amount of certain heavy metals such as copper, iron and manganese catalyze autoxidation reactions. However, this catalytic action can be prevented by applying protective or chelating agent such as metal deactivator like *p*-phenylenediamines.

In the case of vulcanized rubber, the oxidation reaction is more complex than that of raw rubber since the various different types of crosslink (e.g., polysulfidic, disulfidic, monosulfidic, cyclic sulfides, conjugated dienes and treines, etc.) present in the network structure may affect oxidation in some way or another.<sup>16</sup> Most types of sulfur vulcanizates initially hardens on aging before degradation occurs. This hardening is due to cross linking associated with oxidative reactions of sulfur species in the network that takes place before chain scissions take place.<sup>16</sup>

Barnard and Lewis<sup>16</sup> listed out some useful and important points concerning chain scission mechanism for unprotected NR at modest temperature as follows:

- Scission occurs once approximately for every 20 molecules of oxygen absorbed.
- The scission is of the rubber chain even in peroxide or sulfur vulcanizates although concomitant crosslink can occur in the latter.
- Kinetically, scission appears to take place in the propagation step.

- Each scission event results in a stable terminal ketone group being formed on one of the new chains and a transient terminal aldehyde group on the other.

Since autoxidation results in chain scission, means and ways were introduced to determine accurately chain scissions caused by a known quantity of oxygen absorbed. A parameter known as scission efficiency  $\varepsilon$  defined as the number of molecules of oxygen absorbed which bring about one scission event<sup>16</sup> was introduced to monitor chain scission quantitatively. There are two methods either physical or chemical to monitor chain scission. The common physical methods involved measuring molecular weight reduction, stress-relaxation, sol-gel analysis, and stress-strain characteristics.<sup>16</sup> For example, in stress-relaxation method, a rubber sample of a uniform cross-section is held at a constant extension and maintained at a constant temperature. When a network is oxidized due to the cleavage of stress-supporting chains, then the stress would decay and this event would lead to occurrence of stress-relaxation. The change in moles of stress-supporting chains per gram can be calculated from eqn [7]<sup>16</sup>:

$$f_t/f_0 = N_t/N_0 \quad [7]$$

where the subscripts  $t$  and  $0$  refer to the samples after time  $t$  and time zero respectively, and  $f$  derived from the statistical theory of rubber elasticity<sup>18</sup> is given by eqn [8]:

$$f = \rho NRTA_0(\lambda - \lambda^{-2}) \quad [8]$$

where  $\rho$  is the density of rubber,  $N$  is the number of moles of stress-supporting chains per gram,  $R$  is the gas constant,  $T$  is the absolute temperature,  $A_0$  is the unstrained cross-sectional area, and  $\lambda$  is the extension ratio. Stress-relaxation method has the advantage of being able to monitor scission event continuously, and if the amount of oxygen absorbed is also known then the scission efficiency  $\varepsilon$  can be calculated.<sup>16</sup> However, on a short time scale, the decay in stress level as function of time at constant deformation and temperature is associated with the rearrangement of molecular chains and it is predominantly attributed to viscoelastic behavior of the rubber.

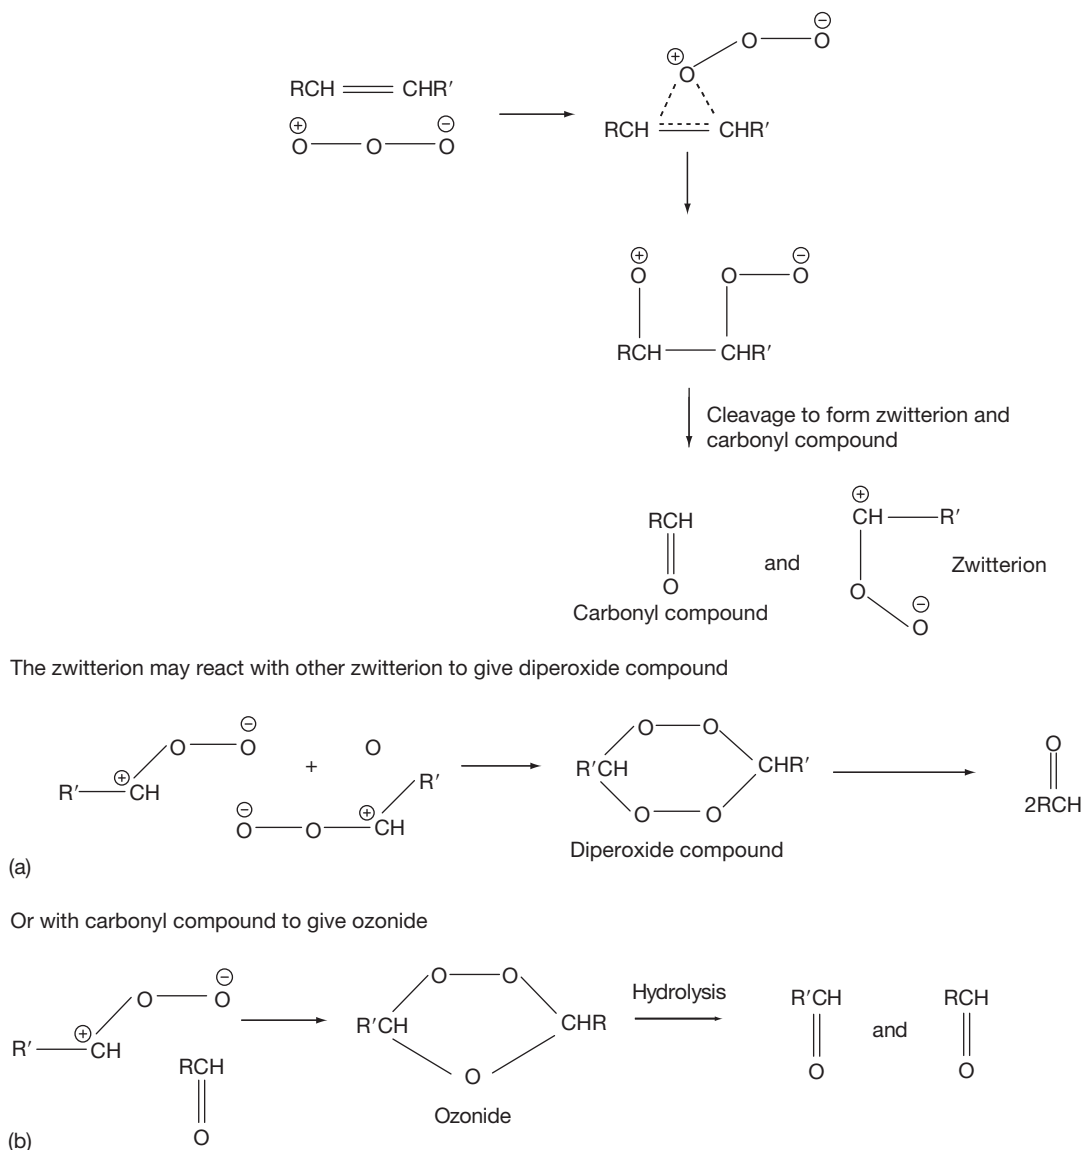

Almost all technical specifications of elastomeric products require passing an aging test. The use of aging tests is extremely important in assessing the service life of elastomeric products because properties of vulcanizate could change during service.

The basic principle of the test is to expose rubber test-pieces to air at an elevated temperature (70 or 100 °C) for a specified period (7 or 14 days or longer). This so-called accelerated aging test causes deterioration of rubber in air due to combined effects of oxidative and thermal aging. The tensile properties, set and hardness are measured on these samples before and after ageing. If minor changes in these properties result, long service life may be expected; if appreciable changes occur, service life may be short. However, it must be stressed here that accelerated ageing test is a useful quality control and specification tests. There are significant difficulties in predicting service life from accelerated aging test. Use of test temperatures much above the anticipated service temperature is not advisable because the correlation between the results of such tests and service performance becomes increasingly tenuous.

### 3.33.7 Ozone Cracking of Rubber

Apart from oxygen, all unsaturated elastomers are also susceptible to ozone attack although ozone concentration in the outdoor atmosphere at ground level is about 1 pphm (part per hundred million of air by volume).<sup>19,20,21</sup> However, this can be significant because the reaction of ozone with the double bond is extremely fast and causes cracking on strained rubber. The cracks appear slowly at right angle to the direction of the strain applied, that grow slowly and consequently lead to a break of the vulcanizate. Ozone being very reactive attacks the double bonds of the rubber and produces ozonide that cleaves to produce zwitterions.<sup>17</sup> The zwitterions are unstable and will breakdown to form other zwitterions. These zwitterions may react with other zwitterions to produce diperoxide compound, or react with carbonyl compound to produce ozonide. In both cases, the ultimate result is chain scission. The mechanism of ozone attack on olefin is as shown in Figure 9.<sup>17</sup>

However, there is a subtle difference between ozone cracking and auto-oxidation where the former requires a certain critical strain level ( $\sim 5\%$  for unprotected NR) for its occurrence.<sup>19,20,21</sup> The severity of ozone cracking increases rapidly with strain level. Braden and Gent,<sup>19</sup> and subsequently Lake *et al.*<sup>20,21</sup> investigated various factors affecting ozone cracking. For example, Lake and Thomas<sup>20</sup> came out with a boundary layer theory for ozone attack on rubber surface to explain the rate of ozone crack growth. According to their theory, the variation in

**Figure 9** Mechanism of ozone attack on olefins.

the rate of ozone attack on stretched rubber surfaces produced by changes in the air velocity and magnitude of the strain is controlled by the diffusion of ozone across the relatively stationary boundary layer adjacent to rubber surface. The boundary layer effect is important because of the readiness with which ozone is destroyed by stretched rubber.<sup>20</sup> As mentioned earlier, ozone cracking occurs only in elastomers subject to tensile stresses. Elastomeric components used in compression will crack only in the regions of the surface where tensile stresses are induced. These cracks are unable to penetrate very

far because they soon encounter compressive rather than tensile stresses. Thus ozone cracking is not a serious problem for large elastomeric components such as rubber bearings which are used in compression. Nevertheless, ozone cracks are unsightly and may initiate fatigue crack growth, which ultimately leads to mechanical failure. In view of this deleterious effect, it is necessary to carry out test on ozone resistance. The test involves exposing the stretched test-pieces (20% strain) in an ozone-rich atmosphere at a fixed temperature (23 or 40 °C) and inspecting the surfaces for cracks with the aid of a magnifying

glass at intervals of time. If cracks are not observed after completion of test, the vulcanizate is said to have good resistance to ozone cracking.

### 3.33.8 Heat Aging Resistance

Elastomers can survive over long periods in service at ambient temperatures without any measurable deterioration if the products are sufficiently thick. For a thick section of rubber, the availability of oxygen will be limited by diffusion, and components with bulky rubber layers can be considerably more resistant to elevated temperatures than thin rubber sections. For example, bearing pads of NR installed in 1890 had been examined, and although the outer 1–2 mm of rubber had degraded after 96 years of exposure to the atmosphere, the inner core of the rubber was still in good condition as shown by the photograph in [Figure 10](#).<sup>2</sup> Rubber samples taken from the interior portion were found to retain good physical properties as that of freshly prepared compounds.<sup>2</sup> At sufficiently elevated temperatures, all types of elastomer will undergo degradation. However, conventional NR vulcanizates can be used safely at 60 °C, the maximum ambient temperature likely to be encountered practice.<sup>2</sup> At temperatures of 300 °C and above, NR vulcanizates first softens as molecular breakdown

**Figure 10** Cross-sectioned view of a 100-year old bridge bearing pad showing the very small depth of penetration of atmospheric degradation. Adapted from Fuller, K. N. G.; Muhr, A. H. *Engineering design with natural rubber*, NR Technical Bulletin, 5th ed.; The Malaysian Rubber Producers' Research Association, London, 1992; pp 1–33, with permission from Tun Abdul Razak Research Centre, Brickendonbury Hertford, England.

occurs, then resinify, becoming hard and brittle.<sup>2</sup> Flammable vapor are emitted and ignition occurs. However, the rate of burning is extremely slowly for the case of large block rubber.<sup>2</sup>

In recent years, new performance demands for automotive elastomers have been proposed<sup>22</sup> to perform at high operating temperatures. This move was made to accommodate increasing concern for improved fuel economy, which resulted in a significant downsizing and redesign of the automobile. Concomitantly the engine compartment became smaller and more difficult to cool thus raising the temperature of the under hood. Current automotive elastomers are expected to perform well under a 120 °C in-service temperature at least until the life of the car.<sup>22</sup>

There is a growing expectation those future automotive elastomers to perform well in a 150 °C environment for over 100 000 miles.<sup>22</sup> This is a clear signal that specialty elastomers would find very strong markets over general-purpose elastomers for high temperature performance.

### 3.33.9 Flex Cracking

Flexing and cyclic stresses can lead to premature failure during service. There are two basic mechanisms of crack growth, (i) ozone crack growth, due to primarily chain scission, and (ii) mechanico-oxidative crack growth, due to mechanical rupture at the tip of a flaw, which is considerably facilitated by the presence of oxygen.<sup>23</sup> Both types of growth can occur under static or dynamic conditions or together. The amount of crack growth in a given time is directly proportional to the ozone concentration. The crack growth rate  $dc/dt$  of a single ozone crack under static conditions is given by [eqn \[9\]](#):

$$dc/dt = \alpha q \quad [9]$$

where  $q$  is the ozone concentration and  $\alpha$  a constant (the rate at unit ozone concentration) which is a property of the rubber.<sup>23</sup> The cyclic crack growth rate is given by [eqn \[10\]](#):

$$r = (dc/dn)_{\text{ozone}} = (F/f_f)\alpha q \quad [10]$$

where  $F$  is the time fraction of cycle for which the test-piece is strained, and  $f_f$  is the frequency.<sup>23</sup> Based on fracture mechanics approach, and assuming that the growth of naturally occurring flaws of a fatigue test has the same characteristics as that of a crack growth test, Lake and Lindley<sup>23</sup> worked out

the fatigue life of vulcanized elastomer as given by eqn [11]:

$$N_f = 1/(16BW_s^2c_0) \quad [11]$$

where  $N_f$  is the number of cycles to failure from a naturally occurring flaw of size  $c_0$ .  $B$  is the crack growth constant, and  $W_s$  is the strain energy density. Thus the fatigue life  $N$  can be predicted from known parameters of eqn [11].

### 3.33.10 Oil Absorption

An unvulcanized elastomer becomes solution when immersed in its solvent; in contrast, a vulcanized elastomer will only swell. The extent of swell depends on the amount of solvent absorbed, which in turn depends on the crosslink concentration and types of solvent. Swelling is undesirable because apart from dimensional instability, the modulus and mechanical strengths are all decreased making the

swollen vulcanizate unsuitable for most engineering applications.<sup>2</sup> In the case of rubber-to-metal bonded, bond failure occurs if the liquid is able to reach the metal plate. **Figures 11 and 12** show some of the typical automotive elastomeric components such as fuel and oil hoses, gaskets, O-rings and seals which are in contact with automotive fuels. These rubber components are thin and susceptible to damages when swollen excessively by the oil. Additives such as ethanol, methanol, and methyl *t*-butyl ether are being placed in gasoline with a view to improve its octane number.<sup>22</sup> Increasing the alcohol content of the gasoline increases the amount of swell, which is very undesirable not only because of dimensional instability, but also reduces tensile strength and elongation at break of the swollen elastomer.

It is well established that swelling is diffusion-controlled and the volume of liquid absorbed is initially proportional to the square root of the time of immersion.<sup>2</sup> For most organic liquids, the rate of penetration depends on their viscosity rather than

**Figure 11** Automotive rubber products in contact with oil and heat: (a) hoses – hydraulic, fuel, gasoline pump, and steam hose and (b) gaskets, O-rings, seals, and exhaust hanger, etc.

**Figure 12** Automotive rubber components: (a) gaskets and (b) O-rings and seals.

their chemical nature<sup>2</sup>. Figure 13 shows the time–viscosity relationship for the liquid to penetrate 5 mm into the rubber interior.<sup>2</sup>

For NR, it takes about 4 days for a volatile liquid such as toluene to penetrate 5 mm depth, 1–2 years for engine lubricating oil, and about 30 years for a petroleum jelly, even with continuous immersion.<sup>2</sup> It is possible to estimate the distance of liquid in a given time provide that the penetration rate is known.<sup>2</sup> Alternatively, the viscosity of the liquid may be used if penetration rate is not known since the penetration rate is related to viscosity as shown earlier in Figure 13.

Southern<sup>24</sup> has introduced a nomogram as illustrated in Figure 14 to facilitate the calculation in estimating the penetration depth of liquid into the elastomer. Although the data were obtained for NR, but would be expected to work with other elastomers of similar  $T_g$ .<sup>24</sup> As an illustration to use the nomogram, Southern<sup>24</sup> has calculated, a liquid with penetration rate of  $7 \times 10^{-5} \text{ cm s}^{-1/2}$  would take 4 weeks to penetrate 1 mm, but 100 years to penetrate 40 mm of the rubber block. The penetration rate–viscosity relationship does not hold for water because of the presence of hydrophilic impurities which complicate transport of water in elastomers.<sup>24</sup>

### 3.33.10.1 Effect of Crosslink Concentration and Polarity on Swelling Resistance

Natural rubber (NR) latex has found very wide applications in the glove industry since the 1920s. This is attributed to the excellent tear and puncture

**Figure 13** Effect of viscosity of liquid on penetration time. Adapted from Fuller, K. N. G.; Muhr, A. H. *Engineering design with natural rubber*, NR Technical Bulletin, 5th ed.; The Malaysian Rubber Producers' Research Association, London, 1992; pp 1–33, with permission from Tun Abdul Razak Research Centre, Brickendonbury Hertford, England.

resistance of NR latex films. Besides, NR latex film exhibits very high extensibility (600–1000%) before its breaking point. These properties make NR latex film an excellent barrier protection against infectious liquids and gases. Most of the examination and surgical NR latex gloves are used in hospitals and clinics. However, recently NR latex gloves have entered the fast food industry where good swelling resistance is an essential requirement. Being a nonpolar rubber, NR latex gloves have a poor swelling resistance which limits its application in the fast-food industry. The fast-food industry is growing very fast all over the world. There is a growing concern over the cleanliness and hygiene of the food. It is essential that the workers wear rubber gloves to avoid contact with the food they serve. Rahim and Samsuri<sup>25</sup> investigated the effect of crosslink concentration and effect of blending carboxylated nitrile rubber (XNBR) with NR latex on the swelling resistance of NR latex film towards cooking oil. The amount of sulfur was varied to produce different crosslink concentrations. The crosslink concentration was determined by immersing the latex film sample in a solvent until equilibrium swelling was attained. The crosslink concentration was calculated by using the Flory–Rehner equilibrium swelling equation as proposed by Mullins<sup>18</sup> given by eqn [12]:

$$-\ln(1 - v_r) - v_r - \chi v_r^2 = 2\rho V_1 [X]_{\text{phy}} v_r^{1/3} \quad [12]$$

where  $v_r$  is the volume fraction of rubber in the swollen gel,  $\rho$  is the density of rubber,  $V_0$  is the molar volume of solvent,  $\chi$  the rubber–solvent interaction parameter, and  $[X]_{\text{phys}}$  is the physically manifested crosslink concentration. The diffusion coefficient  $D$  was calculated from eqn [13]<sup>24</sup>:

$$M_t/M_\infty = (2/l)(Dt/\pi)^{1/2} \quad [13]$$

where  $M_t$  is the total amount of liquid absorbed per unit area of the sheet after immersion for time  $t$ ,  $M_\infty$  is the amount of liquid absorbed after infinite time (in this case time to reach equilibrium swelling), and  $l$  is the half thickness of the film sheet. It is necessary to plot  $M_t$  against square root time as shown in Figure 15 to calculate  $D$  in eqn [13].

The effect of crosslink concentration on the diffusion coefficient of cooking oil in the latex film is shown in Table 8.<sup>25</sup> The results show that increasing the crosslink concentration decreases the diffusion coefficient significantly. Increasing the sulfur content from 0.6 to 3 pphr increases the crosslink concentration by about 90%, which merely decreases the

**Figure 14** Nomogram to facilitate rapid calculation of distance penetrated by liquid into rubber. Adapted from Muniandy, K.; Southern, E.; Thomas, A. G. In *Natural Rubber Science and Technology*; Robert, A. D., Ed.; Oxford University Press, Oxford, UK, 1988; Chapter 13, pp 820–851, with permission from Oxford University Press.

diffusion coefficient by about 23%. However, the most efficient method to increase swelling resistance is through physical blending of NR latex with XNBR latex, where the diffusion coefficient  $D$  of the oil into the film decreases by a factor of 2.7 compared with NR latex having the highest crosslink concentration. Thus, this work shows strong evidence that blending of nonpolar elastomer with polar elastomer enhances the swelling resistance of the former.

### 3.33.11 Water Absorption

Elastomers find wide uses in marine and offshore engineering applications. The application of elastomers

in water management is attributed to its high impermeability to water. A rubber sheet is used to line the water reservoir and pond, while inflatable rubber is used as a dam. Rubber dock fenders rely on the energy absorption capacity of the rubber. Inevitably, the rubber will absorb some quantity of water as these rubber products spend a considerable time under water. It is of great concern whether the absorption of water would impair the strength of the rubber.

The true solubility of water in rubber is very low.<sup>24</sup> Nonetheless, relatively large amounts of water can be absorbed during prolonged immersion as shown in [Figure 16](#).<sup>2</sup> The diffusion of water in elastomers is not straightforward, but complicated by the presence of hydrophilic materials. In the case of NR it is mainly

**Figure 15** Typical mass uptake curve for NR/XNBR blend latex film.<sup>25</sup>

**Table 8** Effect of crosslink concentration on diffusion coefficient  $D$  of cooking oil into NR latex film

Sulfur level (pphr)	$[X]_{phy}$ (mol per kg RH)	$D$ ( $m^2 s^{-1} \times 10^{-13}$ )
0.6	$4.46 \times 10^{-2}$	4.70
1.0	$4.60 \times 10^{-2}$	4.00
2.0	$4.89 \times 10^{-2}$	3.70
3.0	$5.82 \times 10^{-2}$	3.57
NR:XNBR (50:50) 1.5	—	1.30

proteinaceous.<sup>24</sup> When water diffuses into the rubber, the water-soluble hydrophilic materials dissolve forming droplets of solution within the rubber. Osmotic pressure gradient would exist between watery domains in the rubber and that of the external solution immersing the rubber.<sup>24</sup> This results in more water diffusing into the internal solution droplet. Water absorption reaches its equilibrium when the elastic stresses acting on the droplets balance the osmotic pressure difference. Muniandy and Thomas<sup>24</sup> proposed a mathematical model for water absorption to derive equations for the equilibrium water uptake and to evaluate the kinetics of water absorption and desorption. From the model, they calculated the equilibrium water uptake and the apparent diffusion coefficient. They found very good agreement between theory and experimental results.

**Figure 16** Corrected mass uptake measurements for engineering rubbers in seawater at 23 °C: (a) deproteinized NR, (b) lead oxide cured polychloroprene, (c) nitrile rubber, (d) conventional NR, and (e) conventional polychloroprene. Adapted from Fuller, K. N. G.; Muhr, A. H. *Engineering design with natural rubber*, NR Technical Bulletin, 5th ed.; The Malaysian Rubber Producers' Research Association, London, 1992; pp 1–33, with permission from Tun Abdul Razak Research Centre, Brickendonbury Hertford, England.

Later, Lake<sup>26</sup> investigated the kinetics of water (tap water) absorption in elastomers and their effects on properties. He reported that when the absorption was large (50% or more), the rubber test-piece degraded. Severe degradation leads to porosity of the surface layer, and when pressed, water exudes.<sup>26</sup> However, at a low level of absorption, Lake observed

**Figure 17** A natural rubber tire after 40 years' exposure to seawater. Adapted from Mullins, L. *Proc. Int. Rubb. Conf.* Kuala Lumpur, 1985, with permission from Malaysian Rubber Board.

the formation of droplets similar to the blisters that occur in plastics or under protective coatings, consistent with an osmotic diffusion mechanism.<sup>24</sup> In salt-water, water absorption reached steady state at much lower levels than in freshwater, again consistent with an osmotic pressure mechanism. Thus seawater is less damaging than freshwater and may not have any serious consequences for many elastomers. This latter point is consistent with findings of Ab. Malek and Stevenson<sup>27</sup> who evaluated the physical properties of a rubber tire as shown in [Figure 17](#), recovered from seawater at a depth of 80 ft. They found that the rubber tire had absorbed about 5% of seawater after 42 years of immersion. They found no evidence of microbiological attack. What is more interesting, the physical properties of the rubber tire were within normal specifications for new rubber of the same type. They even suggested storing elastomers in deep seawater in view of its inert nature. Indeed, elastomer is a very suitable material to coat metal surfaces against corrosion in deep seawater. The photograph in [Figure 17](#) shows clear evidence that the steel cords making up the bead of the tire are corrosion-free after a 42-year immersion in seawater.<sup>27</sup>

### 3.33.12 Protective Measures

#### 3.33.12.1 Selection of Elastomer

All elastomers experience aging. Some age faster than others. The rate of aging depends on a number of factors such as the chemical structure of the polymer, service environment, which includes length of exposure to heat and light, oxygen and ozone concentration, size and shape of elastomers, and mechanical

stresses. One cannot stop the aging process, but one can slow it down. The most effective means of combating aging is to select the correct elastomers to meet the maximum service temperature and environment. Fully saturated elastomers having high bond dissociation energy making up their backbone chains are the best choice to meet high service temperature applications. Fully saturated rubbers such as ethylene propylene copolymer and very low unsaturation butyl rubber are excellent resistance to heat aging, oxidation and ozone cracking. Not only the maximum service temperature, but also other environmental factor such as oil or solvent determines the aging resistance. In cases like these, the elastomers having high bond dissociation energy and solvent resistance are desired. These include specialty elastomers such as acrylic (ACM), chloro-sulfonyl-polyethylene (CSM), ethylene propylene copolymer (EPM), fluoroelastomers (FKM), silicones (MQ, VMQ), polyester urethanes (AU), etc. Alternatively, for unsaturated elastomers are to use antioxidants and antiozonants, with correct vulcanization system can slow down the aging process quite efficiently.

#### 3.33.12.2 Blends of Elastomers

It is a common practice to blend two elastomers of different properties with a view to combining the best features in terms of technical and economic values. Natural rubber is blended with EPM for applications requiring very high resistance to attack by ozone as the latter is fully saturated. A blend of NR and EPDM is used for applications that require a combination of good resistance to attack by ozone and high

strength properties. Nitrile rubber (NBR) is blended with EPM to meet the requirements for very good oil resistance as well as conferring high resistance to oxidation and ozone cracking. The former is polar rubber and provides very good oil resistance, while the latter provides excellent weather resistance. However, blending two or more elastomers is not as easy as one would imagine. The work on blending various elastomers conducted by Tinker<sup>28</sup> and coworkers has thrown some light on the importance of compatibility, distribution of crosslinks in each rubber phase, distribution of filler and plasticizer and interfacial tension of each phase which have very strong influence on the service performance of the blend. When the elastomers are not compatible with each other, the associated problems that may arise include maldistribution of crosslinks, partition of chemicals (sulfur, accelerators, etc.) due to mechanism associated with preferential solubility and others. Lewan<sup>29</sup> worked on crosslink density distribution in NR/NBR blend and reported the effects of large difference in polarity and solubility parameters between these two rubbers. The large difference in polarity has the following effects:

- (i) causes high interfacial tension that is detrimental to mixing since it interferes with efficient mixing at the interface, hence minimizing the opportunity for crosslinking between the rubbers;
- (ii) causes poor phase morphology, which is characterized by large phase sizes;
- (iii) causes uneven distribution of crosslinks arises through preferential solubility of the curatives and vulcanization intermediates. Sulfur will be preferentially soluble (partition in favor of) the more polar NBR. One phase is over-crosslinked and the other is lowly crosslinked.

However, Lewan<sup>29</sup> overcame these problems by selecting the correct type of curing system such as semi-EV based on sulfur – TBBS, to obtain an even distribution of crosslinks in each phase and maximizing crosslinking between rubbers at the interface. The use of compatibilizer is highly recommended to enhance the compatibility between rubber phases. Polychloroprene rubber serves as a very good compatibilizer for the NR/NBR blend with just a small quantity (5 pphr) added to the blend. The addition of this compatibilizer reduced phase sizes, gave an even distribution of crosslinks and increased tensile strength.<sup>30</sup> Blends of elastomers provide alternative means of improving both aging resistance and oil resistance.

### 3.33.12.3 Antidegradants

Chemical antioxidants and antiozonants combat aging by scavenging harmful radicals, absorbing UV light, deactivating catalytic metals like copper, manganese, iron, etc., and decomposing initiating peroxides.<sup>16,17</sup> Two main types of chemical antioxidants and antiozonants are widely used in rubber compounds; they are amines and phenolics. Amine types are more effective and powerful antioxidants than phenolic types. However, the former is staining and the latter is not. Thus, this limits applications of amine types to black and dark colored elastomeric products. Phenolic types are exclusively used for white and bright colored products, especially in electrical wire insulation where colors are useful for identification purposes. Both amines and phenolics provide protection against aging by scavenging the harmful free radicals during the oxidative chain reaction.<sup>16,17</sup> The proposed mechanism<sup>17</sup> by which these two types of antioxidants work is shown in **Figure 18**. During the initiation stage, the free radicals produced by the peroxides abstract a labile hydrogen atom from the antioxidant and produce an antioxidant radical. This antioxidant radical is more stable than the peroxy radical, which terminates by reaction with other radicals in the system.<sup>16,17</sup>

The transfer step (c) and termination step (f) remove the free radical functionality from the elastomer, which consequently halts the oxidative degradation reaction.<sup>17</sup> Metal deactivators such as 2-mercaptobenzimidazole and its salt when added into the rubber compound containing amine or phenolic antioxidant give a synergistic effect to enhance the protection against aging.<sup>31</sup> These chemicals form

**Figure 18** Mechanism of amine and phenolic antioxidant activity, where AH is the antioxidant.<sup>17</sup>

coordination complexes with catalytic metals and inhibit metal-activated oxidation. Carbon black is a natural UV light absorber, and for nonblack compounds, it is useful to incorporate a UV light absorber such as benzotriazole derivative.

### 3.33.12.3.1 Mechanism of antiozonant action

The mechanism by which an antiozonant protects unsaturated rubber against ozone cracking has received attention from many rubber chemists and physicists. A number of suggestions have been proposed as to how antiozonants confer protection, ranging from competitive reaction with ozone (scavenging) to various types of protective layer formation.<sup>17,19–21</sup> There are three theories to describe the mechanism of antiozonant action<sup>17</sup>:

- (i) The antiozonant blooms to the surface of the rubber compound and reacts preferentially with the incident ozone.
- (ii) The antiozonant blooms to the surface of the rubber and forms a protective layer of film on the surface.
- (iii) The antiozonant reacts with intermediates formed in the ozonation of rubber, preventing chain scission or recombining severed rubber chains.

Lake<sup>32</sup> has conducted some work to elucidate the mechanism of antiozonant action to protect natural rubber against ozone cracking. He used dioctyl-*p*-phenylenediamines (DOPPD) antiozonant for his rubber compound. Exposing the rubber test-piece to ozone-rich atmosphere has reportedly resulted in a layer of film  $10^{-3}$  cm thick and visible to the naked eye forming on the rubber surface.<sup>32</sup> The protective layer can be removed by physical means either by scraping or using adhesive tape, or by swabbing with cotton wool dipped in acetone. The mass of the film can be determined by weighing the test-piece before and after its removal. In this way, the kinetics of layer formation can be determined by monitoring changes in weight after various periods of exposure to ozone.

Lake<sup>32</sup> has derived a mathematical expression to relate the mass of layer per unit area of surface  $M_L$  formed after time  $t$  to the concentration  $C_0$  of antiozonant in the rubber and diffusion coefficient  $D_L$  as shown by eqn [14]:

$$M_L = [2\rho_L D_L S_L C_0 t]^{1/2} \quad [14]$$

where  $\rho_L$  is the density of the layer material and  $S_L$  is the solubility, relative to that in the rubber, of the antiozonant in the layer. In deriving this equation,

Lake<sup>32</sup> assumed that the layer to be formed entirely of reacted antiozonant and the concentration of unreacted material within it to be small. The product  $D_L S_L$  was determined experimentally by measuring the rate of transfer of antiozonant through the layer formed on a test-piece to a controlled rubber test-piece containing no antiozonant initially. This was done experimentally by pressing two cylindrical discs (test-piece A contains antiozonant, test-piece B has no antiozonant) together so their surfaces are in intimate contact with each other. The antiozonant from test-piece A would migrate into test-piece B as a function of time. The mass of the layer formed per unit area of surface was plotted against the square root of time to produce a straight line whose slope gave the value of  $M_L/t^{1/2}$ , that is mass of film deposited per square root time. Lake<sup>32</sup> obtained very good agreement between theory and experimental data.

Lake<sup>32</sup> proposed the mechanism of antiozonant action as follows: The protective layer formed on the rubber surface is composed predominantly of the antiozonant which has reacted with ozone. The film formed remained essentially in the unstrained state, independent of the type of deformation applied. For this to happen, it is necessary that the antiozonant is soluble in the rubber, and that its reaction product should be insoluble. However, once the protective layer becomes coherent and compact, it will reduce substantially the flux of ozone reaching the rubber surface. Thus it appears that the ability of the antiozonant to prevent cracking is likely to be determined by what occurs during the initial stages of exposure when the layer is starting to form, rather than by the long-term behavior. Indeed, Lake<sup>32</sup> suggested that a coherent monomolecular layer of film that formed on the rubber surface is sufficient to confer protection against ozone cracking. However, the time for this monolayer to form must be faster than the time for the crack to grow to the same depth, so that the monolayer is able to bridge any cracks that have begun to grow.

### 3.33.12.3.2 Theories of layer formation

The thin layer of protective film covering the rubber surface is a direct consequence of the chemical reaction between chemical antiozonant and ozone. Lake and Mente<sup>21</sup> proposed two diffusion models to work out a theory for layer formation. The two models are shown in Figure 19. The first model describes the rate of layer formation that is controlled by the diffusion of the antiozonant across the already-formed layer to react with ozone at its outer surface. Under

**Figure 19** Diffusion models for antiozonant layer formation: (a) rate governed by diffusion of antiozonant within the layer only, and (b) rate governed by both diffusion in the layer and in the rubber. Adapted from Lake, G. J.; Mente, P. G. *J. Nat. Rubb. Res.* **1992**, 7(1), 1–13, with permission from Malaysian Rubber Board.

these circumstances, the mass per unit area  $M_L$ , of layer formed after time  $t$  is given by eqn [14].<sup>21,32</sup> The concentration gradient in the layer will be essentially linear as shown in Figure 19(a). The second diffusion model takes into account diffusion within the rubber in addition to diffusion across the layer. In this case, an equation similar to eqn [14] applies, when  $C_0$  is replaced by  $C_s$ , the concentration at the rubber surface is lower than  $C_0$  as shown schematically in Figure 19(b).  $C_s$  is a function of  $C_0$  and the relative permeabilities of the rubber and the layer to the antiozonant, and with the assumptions made, are given by eqn [15]:

$$C_s/C_0 = 1 + \xi - [(1 + \xi)^2 - 1]^{1/2} \quad [15]$$

where

$$\xi = (\pi/4)(\rho_L D_L S_L / D C_0) \quad [16]$$

and  $D$  is the diffusion coefficient of the antiozonant in the rubber. The mass of layer per unit area of surface plotted against square root of time as shown in Figure 20 enabled Lake and Mente<sup>21</sup> to determine the rates of layer formation of the antiozonants formed on NR, ENR 50, and NBR 34, respectively. These three rubbers differ greatly in terms of

**Figure 20** Dependence of the mass of antiozonant layer formed on the square root of the time of exposure to an ozone concentration of 200 pphm at 40 °C for vulcanizates of NR, ENR 50, and NBR 34. Adapted from Lake, G. J.; Mente, P. G. *J. Nat. Rubb. Res.* **1992**, 7(1), 1–13, with permission from Malaysian Rubber Board.

polarity and glass-transition temperature, which may affect the rate of film formation on the rubber surface. Their experimental results as shown in Figure 20 indicate that the rate of layer formation for NR is about four times faster than that of NBR 34 and ENR 50, which is in accordance with the dependence of the diffusion coefficient on the glass-transition temperature of the rubber. The diffusion coefficient decreased in the increasing order of the  $T_g$  of the rubber.<sup>21</sup> Thus the diffusion coefficient of NR is fastest and that of ENR 50 is the slowest as  $T_g$  of NR is about  $-69$  °C and that of ENR 50 is about  $-24$  °C.<sup>21</sup> NBR34 has a slightly faster diffusion coefficient than ENR 50 as its  $T_g$  ( $-28$  °C)<sup>19</sup> is slightly lower than that of ENR 50. Lake and Mente<sup>21</sup> also conducted experiments to investigate the effect of temperature on layer formation on the NR surface at  $-17$  and  $23$  °C respectively as shown in Figure 21. They found that the rates of layer formation at these two temperatures were the same for NR. However, the diffusion coefficient of this particular antiozonant (DOPPD) in NR at  $-17$  °C was very similar to that in ENR 50 and NBR 34 at  $23$  °C. They attributed this finding to the partitioning of the antiozonant

**Figure 21** Mass of antiozonant layer formed versus square root of the time of exposure to  $10^5$  pphm ozone for an NR vulcanizate containing 10 phr DOPPD at 23 and  $-17^\circ\text{C}$ . Adapted from Lake, G. J.; Mente, P. G. *J. Nat. Rubb. Res.* **1992**, 7(1), 1–13, with permission from Malaysian Rubber Board.

between the elastomer and the layer material, as the polarity of the elastomer affects the solubility of the antiozonant in the rubber. The solubility of the antiozonant varies in the ascending order of polarity of elastomer, that is  $\text{NR} < \text{NBR } 34 < \text{ENR } 50$ .<sup>21</sup> Lake and Mente concluded that for elastomers with high  $T_g$ , the antiozonant offers better protection at temperatures above room temperature than at low temperature, as the protective agents are more mobile at high temperatures rather than at low temperatures.

### 3.33.12.4 Blooming of Wax

Besides chemical antiozonants, paraffin wax is also a useful ingredient to confer protection against ozone cracking. Wax provides a protective layer surrounding the surface of the elastomer through the diffusion process commonly known as blooming, which prevents direct contact between ozone and the elastomer. Blooming occurs when the supersaturated solution of the ingredient in the rubber crystallizes more readily on the surface than in the rubber itself.<sup>24,33</sup> This basic mechanism of blooming is not only applicable to wax but other ingredients as well. When other ingredients such as sulfur, accelerators and stearic acid bloom to the rubber surface, they reduce the tackiness of the rubber, which can bring detrimental effects to

products relying on adhesion and bond strength involving different components plied together. These include rubber-to-metal bonded components, tires, belts, and hoses. However, blooming of waxes and antioxidants brings advantages.

Nah and Thomas<sup>33</sup> investigated the mechanism and kinetics of diffusion of wax to the rubber surface. They envisaged that the driving force for the blooming process arises from the elastic forces acting around the wax precipitates in the rubber when the wax concentration is in excess of its equilibrium solubility. They then proposed a model and theory for wax blooming base on thermodynamic concept of diffusion, where the driving force of the diffusion process is predominantly associated with free energy gradient rather than the concentration gradient of the wax that is dissolved in the rubber. The initial rate of wax bloom per unit area ( $M_t/t^{1/2}$ ) is given by eqn [17]<sup>33</sup>:

$$(M_t/t^{1/2})_{x=0} = [(24v_f D_t s_x \rho_x V_x G)/RT]^{1/2} (d\lambda/dy)_0 \quad [17]$$

where  $D_t$  is diffusion coefficient,  $v_f$  is volume fraction of seeding particles or flaws present in the rubber.  $s_x$  is solubility of wax in the rubber,  $\rho_x$  is density of wax, and  $V_x$  is molar volume of solid wax.  $G$  is shear modulus of the rubber,  $R$  is molar gas constant,  $T$  is absolute temperature.  $(d\lambda/dy)_0$  is equivalent to the concentration gradient of the wax at the surface of the rubber, and is determined by numerical methods for the appropriate boundary conditions and a suitable value of  $v_f$ . The symbol  $\lambda$  stands for the extension ratio of the rubber around the precipitated wax particle, assumed spherical. Nah and Thomas<sup>33</sup> verified eqn [17] experimentally, and obtained satisfactory agreement between their experimental and theoretical values for the migration of paraffin waxes in peroxide cured natural rubber. The theory was applicable to predict the blooming of wax mixtures with success, indicating that the mechanism of wax blooming has been identified correctly. Although Nah and Thomas developed the theory for blooming of wax, with minor adjustments, it is also applicable to predict migration and blooming of sulfur, fatty acids and antidegradants in vulcanized elastomers.

### 3.33.12.5 Choice of Vulcanization System

Anaerobic aging usually decreases the stiffness, resilience, and tensile, tear and fatigue properties; the extent is mainly determined by the type of vulcanization system, which affects aging of elastomers. There are three types of sulfur vulcanization systems known as conventional, efficient (EV) and

semi-efficient (semi-EV) respectively<sup>8,10</sup> as discussed briefly in [Section 3.33.4.3](#). The conventional system has a higher sulfur dosage than the accelerator that produces predominantly polysulfidic crosslinks, where the rubber molecular chains are linked by three or more sulfur atoms. Polysulfidic crosslinks have poor resistance to heat aging because the  $-S-S-$  bond has low thermal stability. In contrast, EV makes use of the low sulfur level and high accelerator dosage. This EV system produces predominantly monosulfidic crosslinks which are thermally very stable. The rubber network consists of other structural features as described briefly in subsequent sections.

### **3.33.12.5.1 Sulfur vulcanization system and types of crosslinks on aging resistance**

#### **Polysulfidic crosslink**

A chain of three or more sulfur atoms (maximum of six atoms) in this crosslink bridges two polymer chains. The bond energy of this crosslink is less than  $268 \text{ kJ mol}^{-1}$ , which is relatively low.<sup>10</sup> A polysulfidic crosslink can be produced by using the conventional vulcanization system where the quantity of sulfur is more than the quantity of the accelerator in the ratio 5:1 (sulfur: accelerator). Therefore the conventional sulfur cure system is not suitable for high temperature applications.

#### **Disulfidic crosslink**

In a disulfidic crosslink, there are two sulfur atoms bridging the two polymer chains. Its bond energy is about  $268 \text{ kJ mol}^{-1}$ . Little is known of the properties of this crosslink, mainly because it is very difficult to prepare a network in which disulfides are predominant. In both conventional and efficient sulfur vulcanizes the proportion of disulfidic crosslink is seldom more than 20–30% of the total.

#### **Monosulfidic crosslink**

In the case of a monosulfidic crosslink, the two polymer chains are bridged by one sulfur atom. Its bond energy<sup>10</sup> is relatively high, about  $285 \text{ kJ mol}^{-1}$ . A monosulfidic crosslink can be produced from an EV system where the amount of the accelerator is higher than the amount of sulfur, about 5:1 (accelerator:sulfur). Thus the EV system is suitable for medium high temperature applications.

#### **Cyclic sulfides**

These are intra-crosslinks which are useless as the crosslinks are formed on the same polymer chain.

This phenomenon is also known as main chain modification. The main source of these main chain modifications is the thermal decomposition of polysulfide crosslinks. The conventional vulcanization system creates more cyclic sulfides than the EV system as the former produces more polysulfide crosslinks than the latter.

#### **Conjugated diene and triene groups**

These main chain modifications are also formed by the thermal decomposition of polysulfide crosslinks. The concentration of these conjugated groups increases on overcure. The presence of these groups tends to catalyze oxidative aging as they are much more susceptible to oxidation than the polyisoprene main chain.<sup>8,10,16</sup>

#### **Pendent accelerator group**

It is generally accepted that in accelerated sulfur vulcanization, crosslinks are formed from initial rubber-bound pendent groups in which disulfide or polysulfide chains are terminated by accelerator fragments. Like the crosslink, some of these intermediates undergo progressive desulfuration and are converted into stable monosulfidic links between the polymer chain and accelerator fragments. The extent of main chain modification will depend on the amount of accelerator available and on the ease with which the initial pendent group can be desulfurated.

#### **Extra-network material**

The extra-network material formed by a sulfur vulcanizing system can be put into two categories. The first consists of unreacted zinc oxide and fatty acid activators, their zinc soap reaction products and zinc sulfide. The second consists of accelerator reaction products.

### **3.33.12.5.2 Peroxide vulcanization system**

Unlike sulfur vulcanization, peroxide vulcanization does not require the presence of double bonds. In fact, peroxide vulcanization is possible for rubbers having either saturated or/and unsaturated carbon-carbon backbone chains. However, peroxide vulcanization is quite impossible with the following elastomers because of their tendency to decompose:

- IIR – butyl rubber
- CIIR – chlorinated butyl rubber
- CO – polyepichlorohydrin rubber
- ECO – copolymer of epichlorohydrin and ethylene oxide
- PP – polypropylene
- ACM – polyacrylic rubber

The most common peroxide is dicumyl peroxide (DCP or dicup). Others include ditert butyl peroxide, dibenzoyl peroxide and bis(2,4-dichlorobenzoyl) peroxide. Peroxide vulcanization<sup>10</sup> produces a vulcanizate which will impart good aging resistance and excellent resistance to compression at high temperatures (70–100 °C). To obtain the best compression set performance, freedom from certain other compounding ingredients, especially zinc oxide and stearic acid, is essential. Peroxide vulcanization is essentially nonreverting. However, there are certain deficiencies such as poor hot tear strength and incompatibility with chemical antiozonants. Other technical limitations include slow cure rate with no delayed action, and degradation of the rubber giving a sticky surface if it comes into contact with air during the cure. Thus peroxides are not suitable for hot-air or steam-pan curing. The reaction of peroxide must be carried through to completion to obtain the best heat resistance; therefore long cure times are inevitable. In addition, nearly all antidegradants and aromatic oils affect the efficiency of the peroxide cure.

Co agents, which are highly reactive materials, are usually added in peroxide vulcanization to increase the efficiency of the organic peroxide, but do not affect the rate of cure.<sup>10,31</sup> They are used either to enhance the modulus and hardness or to reduce the level of peroxide required. They can be absolutely essential for the efficient cure of chlorinated polyethylene. Typical solid coagents are zinc diacrylate, zinc dimethacrylate, and *m*-phenylene dimaleimide. Liquid coagents are materials such as triallyl cyanurate (TAC), triallylisocyanurate (TAIC), etc. High vinyl polybutadiene is a polymer which can act as a coagent.

### 3.33.12.5.3 Vulcanization with urethane

This (urethane) crosslinking system for natural rubber was developed in the early 1980s by the scientists at the Malaysian Rubber Producers Research Association (MRPRA).<sup>10,31</sup> It was marketed under the trademark Novor. The basic reagent is a reaction product of a nitroso compound and a diisocyanate which dissociates at vulcanizing temperatures into its component species. The free nitroso compound then reacts by addition to rubber molecules giving attached pendent groups which subsequently react with the diisocyanate to form urea type crosslinks. The main features of the vulcanizates are excellent reversion resistance and, when protected with a TMQ/ZMBI antioxidant combination, excellent heat aging resistance.

### 3.33.12.5.4 Metallic oxide vulcanization

Elastomers containing halogens can be cured with metallic oxides such as oxides of zinc, magnesium, and lead. The oxides form an ether type of crosslink (R–O–R') which gives good heat aging resistance. Elastomers which can be vulcanized with metallic oxides are polychloroprene, halogenated butyls, and polychlorosulphonated rubber.

### 3.33.12.5.5 Resin vulcanization

Resin vulcanization has established itself to some degree in butyl (IIR) crosslinking, giving excellent heat and steam stability.<sup>10</sup> Example of a typical resin cross linker is polymethylolphenolic resin. The amount used is at the level of 5–12 pphr.

### 3.33.12.5.6 Quinonedioximes vulcanization

*p*-Benzoquinonedioxime (CDO) as well as its dibenzoyl derivative are cross linkers for many rubbers because of their free radical reactions.<sup>10</sup> Best known and of greatest interest is their use in IIR because of the excellent heat and steam stability that can be obtained. They are used mainly for rubbers having low unsaturation where sulfur vulcanization is slow. They have been unimportant for the classic diene rubbers.

## 3.33.13 Future Developments in Materials or Applications

Natural rubber and synthetic elastomers are likely to maintain their roles and contributions in domestic and industrial applications, buildings and structures, automobiles, and marine and engineering products. With the emergence of nanomaterials for rubber compounding, it is envisaged that future elastomeric products will provide better service and longer life performance than they are capable of providing now. High heat resistant elastomers and highly oil resistant elastomers are the main players of the future to meet the high demands of the automotive industry and aeronautical engineering. More developmental work in these areas is expected.

## Acknowledgements

I am very grateful to Dr. Stuart Lyon, Reader in Corrosion Control Engineering, School of Materials (Corrosion and Protection Centre), University of Manchester, England, who gave me the opportunity to write as part the prestigious Shier's Corrosion

book. I feel much honored to be among the experts who contributed to this fourth edition of Shier's Corrosion.

It gives me great pleasure to thank the Publication Divisions of the Malaysian Rubber Board (MRB) (formerly Rubber Research Institute of Malaysia), and its sister concern the Tun Abdul Razak Research Centre (TARRC) (formerly Malaysian Rubber Producers Research Association) at Brickendonbury Hertford, England. In particular, Dato' Dr. Kamarul Baharin Basir, Director General, MRB and Mdm Rabeatun Awaliah Awalludin, MRB, and Dr. A.J. Tinker (Director Research) TARRC and Ms. K. Lawson TARRC who helped me to obtain the permission to reproduce data and figures from their respective Publication Divisions.

I would like to express my sincere appreciation and thanks to Oxford University Press and the American Chemical Society (Rubber Division) for giving permission to reproduce figures and data from their respective publications.

Last but not least, Associate Prof. Dr. Mohamad Kamal Harun, Dean of Faculty of Applied Sciences, MARA University of Technology, Malaysia (UiTM) for his encouragement.

### Glossary

**Bead** A single run of weld metal on a surface.

**Brazing** A metal joining process that is identical to soldering except that the joining takes place at temperatures generally above 500 °C. The molten non-ferrous filler metal is distributed between properly fitted surfaces of the joint by capillary attraction.

**Butt joint** A connection between the ends or edges of two parts making an angle to one another of 135°–180° inclusive in the region of the joint.

**Edge preparation** The preparation of an edge, by squaring, grooving, chamfering, or bevelling, prior to welding.

**Electroslag welding** A fusion welding process that utilizes the combined effects of current and electrical resistance in a consumable electrode and conducting bath of molten slag, through which the electrode passes into a molten pool, both the pool and the slag being retained in the joint by cooled shoes which move progressively upwards.

**Electron-beam welding** A welding process in which the joint is made by fusing the parent metal by the impact of a focused beam of electrons.

**Filler metal** The metal that is added during welding, braze welding, brazing, or surfacing.

**Flux** A material that is used during welding, brazing, or braze welding to clean the surfaces of the joint, prevent atmospheric oxidation, and to reduce impurities.

**Friction welding** A welding process by which the joint metals are fused together by the conjoint action of frictional heating and pressure.

**Fusion penetration** The depth to which the parent metal has been fused.

**Fusion zone** That part of the parent metal which is melted into the weld metal.

**Heat affected zone** That part of the parent metal that is metallurgically affected by the heat of the joining process, but not melted.

**Laser welding** A welding process employing a laser as the source of heat.

**Metal arc welding** An arc welding process that uses a consumable metal electrode.

**MIG welding** Metal-inert gas arc welding using a consumable electrode.

**Gas welding** A welding process in which the heat source is a flammable gas (commonly acetylene) that is burnt in an oxygen atmosphere.

**Parent metal** The metal that is to be joined.

**Pressure welding** A welding process in which a weld is made by a sufficient pressure to cause plastic flow of the surfaces, which may or may not be heated.

**Resistance welding** A welding process in which force is applied to surfaces in contact and in which the heat for welding is produced by the passage of electric current through the electrical resistance at, and adjacent to, these surfaces.

**Run** The metal melted or deposited during one passage of an electrode, torch, or blow-pipe.

**Soldering** A metal joining process that is identical to brazing except that the joining takes place at temperatures generally below 500 °C. The molten nonferrous filler metal is distributed between closely fitted surfaces of the joint by capillary attraction.

**Submerged arc welding** Metal-arc welding in which a bare wire electrode is used; the arc is enveloped in flux, some of which fuses to form a removable covering of slag on the weld.

**TIG welding** Tungsten inert-gas arc welding using a nonconsumable electrode of pure or activated tungsten.

**Thermal cutting** The parting or shaping of materials by the application of heat with or without a stream of cutting oxygen.

**Weld** A union between pieces of metal at faces rendered plastic or liquid by heat or by pressure, or by both. A filler metal whose melting temperature is of the same order as that of the parent material may or may not be used.

**Welding** The making of a weld.

**Weld metal** All metal melted during the making of a weld and that is retained in the weld.

**Weld zone** The zone containing the weld metal and the heat-affected zone.

## Abbreviations

**CP** Cathodic protection

**HAZ** Heat affected zone

**IGA** Intergranular attack

**MIG** Metal inert gas

**MMA** Manual metal arc

**PWHT** Postweld heat treatment

**SCC** Stress corrosion cracking

**SSCC** Sulfide stress corrosion cracking

**TIG** Tungsten inert gas

### 3.35.1 Introduction

A jointed fabrication is the one in which two or more components are held in position by one of:

1. A mechanical fastener (screw, rivet, bolt, etc.).
2. A fusion joining process (e.g., welding, brazing, soldering, etc.).
3. An adhesive bond.

The components of the joint may be metals of similar or dissimilar composition and structure, metals and nonmetals, or they may be wholly nonmetallic. Since the majority of fabrications are joined at some stage of their manufacture, the corrosion behavior of joints is of utmost importance, and the nature of the materials involved in the joint, and in the geometry of the joint, may lead to a situation in which one of the materials is subjected to accelerated and/or localized attack. Although galvanic corrosion is dealt with elsewhere in this book, it is necessary to emphasize the following in relation to corrosion at joints in which the metals involved may be either identical or similar:

1. A difference in electrochemical potential may result from differences in structure or stress brought about during or subsequent to the joining process.
2. Large differences in area may exist in certain jointed structures, for example, between weld metal and parent metal.
3. Many joining processes lead to a crevice, with the consequent possibility of crevice corrosion.

The corrosion of adhesive joints is described in a separate chapter in this book.

### 3.35.2 Mechanical Fasteners

These require little further description and take the form of bolts, screws, rivets, etc. Mechanical failure may occur as a result of the applied stress in shear or tension exceeding the ultimate strength of the fastener, and can normally be ascribed to poor design. However, other failure modes are possible, including the failure of steel fittings below their ductile-to-brittle transition temperature, or by hydrogen embrittlement. Also, failure mechanisms that combine mechanical and corrosion aspects are of particular risk, that is, corrosion fatigue, stress corrosion cracking (SCC), etc. Thus, the corrosion problems associated with mechanical fixtures are often one of three types, that is, crevice corrosion, galvanic corrosion, or stress related.<sup>1-3</sup> Individually, these topics are dealt with in some detail in the relevant chapters elsewhere in this book.

As an example, the mechanical joining of aluminum alloys to steel using rivets and bolts, a combination which is difficult to avoid in the shipbuilding industry, represents a typical example of a situation where subsequent galvanic corrosion could occur. Similarly, other examples of an ill-conceived choice of materials, which should normally be avoided, can

be found in, for example, brass screws used to attach aluminum plates or steel pins used in the hinges of aluminum windows.

The relative areas of the metals being joined is of primary importance in galvanic corrosion. For example, stainless steel rivets can be used to join aluminum sheet (small cathode, large anode), whereas the reverse situation would lead to rapid deterioration of aluminum rivets (large cathode, small anode). However, in the former case a more dangerous situation could arise if a crevice was present, for example, a loose rivet, since under these circumstances the effective anodic area of the aluminum sheet would be reduced, with consequent localized attack. In general, under severe environmental conditions, it is always necessary to insulate the components from each other by use of insulating washers, sleeves, gaskets, etc. as shown in [Figure 1](#). The greater the danger of galvanic corrosion, the greater the necessity to ensure complete insulation; washers may suffice under mild conditions but a sleeve must be used additionally when the conditions are severe.<sup>4</sup>

The fasteners themselves may be protected from corrosion and made compatible with the metal to be fastened by the use of a suitable protective coating, for example, a metallic or organic coating, etc. The choice of fastener and protective coating, or the materials from which it is manufactured, must be made in relation to the components of the joint and environmental conditions prevailing. A point that cannot be overemphasized is that, in the long term, stainless steel fasteners should always be used for securing joints of stainless steel parent metal.

In the case of protection with organic coatings, it is dangerous to confine the paint to the more anodic component of the joint because if the paint is scratched, intense localized attack is likely to occur on the exposed metal. In general, organic coatings should be applied to both the anodic and cathodic metal, but if this is not possible, the more cathodic metal rather than the more anodic metal should be painted. The use of high-strength steels for bolts for fastening mild steel does not normally present problems, but a serious situation could arise if the structure is to be cathodically protected, particularly if an impressed current system is to be used, since failure could then occur by hydrogen embrittlement; in general, the higher the strength of the steel and the higher the stress, the greater the susceptibility to cracking.

In summary, mechanical joints are important joining methods. However, attention must be given to materials compatibility in order to avoid dissimilar metal

**Figure 1** Design of insulated joints. Reproduced from Layton, D. N.; White, P. E. *Br. Corros. J.* **1966**, 1(6), 213.

corrosion problems, crevice corrosion, for example, for aluminum,<sup>5,6</sup> stress corrosion, and corrosion fatigue.

### 3.35.3 Soldering and Brazing

These metal joining processes are essentially identical apart from the temperature of joining, which is lower for soldering (generally below  $\sim 500^\circ\text{C}$ ) than for brazing (generally above  $\sim 500^\circ\text{C}$ ). A characteristic of both processes is the formation of an interdiffusion layer between the parent and filler metal that, if properly formed, constitutes the main metallurgical bond, which results in the strength of the joint. Since a filler material is used for joining which is necessarily different from the parent metal, galvanic corrosion is one of the characteristic failure mechanisms.

#### 3.35.3.1 Soldered Joints

Soldering and brazing are methods of joining components together with a lower-melting-point alloy such that the parent metal (the metal or metals to be joined)

is not melted. Traditional alloys for this purpose are summarized in [Table 1](#), although it should be noted that many of the lead-containing alloys are no longer in use. In the case of soft soldering, the maximum temperature employed is usually of the order of  $250^\circ\text{C}$ , and the filler alloys used for joining are generally based on a tin alloy composition. The components must present a clean surface to the solder to allow efficient wetting and flow of the molten filler and to provide a joint of adequate mechanical strength. To obtain the necessary cleanliness, degreasing and mechanical abrasion may be required followed by the use of a flux to remove any remaining oxide film and to ensure that no tarnish film develops on subsequent heating.

Soldered joints present their own characteristic corrosion problems usually in the form of dissimilar metal attack often aided by inadequate flux removal after soldering. Such joints have always been a source of concern to the electrical industry.<sup>7,8</sup> However, in view of the toxicity of lead and its alloys, the use of lead solders, particularly in contact with potable waters and foodstuffs, is effectively no longer permitted.

**Table 1** Traditional soldering and brazing alloys

<i>Process</i>	<i>Temperature range(°C)</i>	<i>Typical fillers</i>	<i>Fluxes</i>
Soldering Hot iron, oven, induction, ultrasonic, dip, resistance, wave and cascade	60–300	70Pb–30Sn 40Pb–60Sn 70Pb–27Sn–3Sb 40Pb–58Sn–2Sb Sn–Zn–Pb	Chloride based Fluoride based Resin based
Brazing Torch, dip, salt bath, furnace, induction, resistance	500–1200	90Al–10Si 50Ag–15Cu–17Zn–18Cd Ag–Cu–Ni–In 60Ag–30Cu–10Zn 50Cu–50Zn 97Cu–3P 70Ni–17Cr–3B–10Fe 82Ni–7Cr–5Si–3Fe 60Pd–40Ni	Borax based Fluoride based Hydrogen gas Town's gas Vacuum

In the case of carbon and stainless steels, and many of the nonferrous alloys, the fluxes are based on acidic inorganic salts, for example, chlorides, which are highly corrosive to the metal unless they are removed subsequently by washing in hot water. For soldering tinplate, copper, and brass, it is possible to formulate resin-based fluxes having noncorrosive residues, and these are essential for all electrical and electronic work. Activators are added to the resin to increase the reaction rate, but these must be such that they are thermally decomposed at the soldering temperature if subsequent corrosion is to be avoided.<sup>9</sup> Corrosion is always a particular risk with soldered joints in passive materials such as aluminum owing to the relatively large difference in electrochemical potential between the filler alloy and the parent metal and the highly corrosive nature of the flux that is generally used for soldering. With aluminum soldering, it is imperative that the joints be well cleaned both prior and subsequent to the soldering operation, and the design should avoid subsequent trapping of moisture.

### 3.35.3.2 Brazed Joints

When stronger joints or higher temperature service are required, brazing may be used.<sup>10</sup> The filler alloys employed generally melt at much higher temperatures (600–1200 °C), but the effectiveness of the joining process still depends upon surface cleanliness of the components to ensure adequate wetting and spreading. Metallurgical and mechanical hazards may be encountered in that the filler may show poor spreading or joint filling capacity in a certain situation or may suffer from

hot tearing, whilst during furnace brazing in hydrogen-containing atmospheres there is always the possibility that the parent metal may be susceptible to hydrogen embrittlement or steam cracking. Furthermore, brittle diffusion products may be produced at the filler base-metal interface as a result of the reaction of a component of the filler alloy with a base-metal component, for example, phosphorus-bearing fillers used for steel in which the phosphorus diffuses into the steel.

Damage during the brazing procedure can be caused by excessive diffusion into the parent metal of the molten brazing alloy, especially where the parent contains residual or applied stresses, which can lead to liquid metal embrittlement. Nickel and nickel-rich alloys are particularly prone to liquid-braze-filler attack especially when using silver-based braze fillers at temperatures well-below the annealing temperature of the base metal, since under these conditions there is no adequate stress relief of the parent metal at the brazing temperature. The problem may be avoided by annealing prior to brazing and ensuring the maintenance of stress-free conditions throughout the brazing cycle. A range of silver-, nickel-, and palladium-based braze fillers of high oxidation and corrosion resistance have been developed for joining the nickel-rich alloys; however, the presence of sulfur, lead, or phosphorus in the base-metal surface or in the filler can be harmful, since quite small amounts can lead to interface embrittlement. In the case of nickel–copper alloys, the corrosion resistance of the joint is generally less than that of the parent metal and the design must be such that as little as possible of the joint is exposed to the corrosive media.

With carbon and low-alloy steels, the braze fillers are invariably noble to the steel so that there is less likelihood of corrosion (small cathode/large anode system). However, for stainless steels a high-silver braze filler alloy is often used to retain the corrosion resistance of the joint. However, embrittlement of the filler is always a possibility if any zinc, cadmium, or tin are present. An interesting example of the judicious choice of braze filler is to be found in the selection of silver alloys for the brazing of stainless steels to be subsequently used in a tap-water environment.<sup>11</sup> Although the brazed joint may appear to be quite satisfactory, after a relatively short exposure period, failure of the joint occurs by a mechanism which appears to be due to the breakdown of the bond between the filler and the base metal. Dezincification is a prominent feature of the phenomenon<sup>12,13</sup> and zinc-free braze alloys based on the Ag–Cu system with the addition of nickel and tin have been found to inhibit this form of attack. A similar result is obtained by electroplating of nickel over the joint area prior to brazing with a more conventional Ag–Cu–Zn–Cd alloy. Interface corrosion of brazed stainless steel joints has been reviewed by Kuhn and Trimmer,<sup>14</sup> whilst Lewis<sup>15</sup> has used X-ray photo-electron spectroscopy to confirm the dezincification theory. On the other hand, the corrosion resistance of a high temperature brazed joint in a Mo-containing low-C stainless steel exposed to drinking water gave no problems.<sup>16</sup>

When, in an engineering structure, an aluminum–bronze alloy is selected for corrosion resistance, the choice of braze filler becomes important. Thus, although copper–zinc brazing alloys are widely used, the corrosion resistance of the resultant joint (effectively of brass) will be significantly worse than that of the bronze. Crevice corrosion has also been found when joining copper tubes using Cu–Ag–P fillers, the presence of scale adjacent to the joint being deemed responsible.<sup>17</sup> Brazing with copper alloys is unsuitable for equipment exposed to ammonia and various ammoniacal solutions because of the likelihood of increased corrosion, especially SCC with copper- and nickel-base alloys; however, an alloy based on Fe–3.25B–4.40Si–50.25Ni has been shown to be suitable for such applications.<sup>18</sup>

### 3.35.4 Welded Joints

#### 3.35.4.1 Welding Processes

A weld differs from all other forms of joint in that the intention is to ideally obtain a homogeneous material

(i.e., continuous and of similar microstructure and composition) throughout the volume of the welded joint. There are a large variety of processes by which this may be achieved, most of which depend upon the application of thermal energy to bring about a plastic or molten state of the metal surfaces to be joined. The more common processes used are classified in **Table 2**.

Examination of a welded joint shows several distinct zones, namely the fusion zone with its immediate surroundings, the heat affected zone (HAZ) adjacent, and the parent metal that remains unaffected, **Figure 2**. It is apparent that welding necessarily produce differences in microstructure between the (effectively) cast deposit, the HAZ which has undergone a variety of thermal cycles, and the parent plate. Furthermore, differences in chemical composition are often present between parent and weld metal. Other characteristics of welding include:

1. The production of a residual stress system which remains after welding is completed, and which, in the vicinity of the weld, is tensile and can exceed yield.
2. In the case of fusion welding, the surface of the deposited metal has a generally rough surface profile that is both a stress raiser and a site for the condensation of moisture.
3. The joint area is covered with an oxide scale and possibly a slag deposit which may be chemically reactive, particularly if hygroscopic.
4. Protective coatings on the metals to be joined are inevitably removed during welding so that the weld and the parent metal in its vicinity become unprotected compared with the bulk of the plate.

**Table 2**     Typical joining processes

<i>Joining process</i>	<i>Types</i>
Mechanical fasteners	Nuts, bolts, rivets, screws
Soldering and brazing	Hot iron, torch, furnace, vacuum
Fusion welding	Oxyacetylene, manual metal arc, tungsten inert gas, metal inert gas, carbon dioxide, pulsed arc, fused arc, submerged arc, electro slag, and electron beam
Resistance welding	Spot, seam, stitch, projection, butt, and flash butt
Solid-phase welding	Pressure, friction, ultrasonic and explosive

**Figure 2** Weld definitions. (a) fusion weld and (b) resistance spot weld.

Therefore, the use of welding as a method of fabrication may modify the corrosion behavior of an engineering structure, and this may be further aggravated by removal of protective systems applied before welding, whilst at the same time the use of such anticorrosion coatings may lead to difficulties in obtaining satisfactorily welded joints.<sup>19–21</sup>

### 3.35.4.2 Weld Defects

There is no guarantee that defect-free joints will automatically be obtained when fabricating 'weldable' metals. This is a result of the fact that weldability is not a specific material property but a combination of the properties of the parent metals, filler metal (if used), and various other factors that are summarized in Table 3.<sup>22</sup> The consequence of the average structural material is to produce a situation where defects may arise in the weld deposit or HAZ, as summarized in Table 3 and Figure 3.

It is obvious that these physical defects are dangerous in their own right but it is also possible for them to lead to subsequent corrosion problems, for example, pitting corrosion at superficial nonmetallic inclusions and crevice corrosion at pores or cracks. Other weld irregularities which may give rise to crevices include the joint angle, the presence of backing strips and spatter, as summarized in Figure 4 and Table 4.

**Table 3** Factors affecting weldability after Lundin

Parent metal	Filler metal	Other factors
Composition	Composition	Degree of fusion (Joint formation)
Thickness	Impact strength	Degree of restraint
State of heat treatment	Toughness	Form factor (Transitions)
Toughness	Hydrogen content	Deposition technique
Temperature	Purity	Skill and reliability of the welder
Purity	Homogeneity	
Homogeneity	Electrode diameter (heat input during welding)

**Figure 3** Possible weld defects.

### 3.35.4.3 Factors Affecting Weldment Corrosion

Corrosion of welds may result from one or more of a number of factors, including:

1. Deficient weld design
2. Residual stresses
3. Inadequate consumables
4. Deficient welding procedure or welding technique
5. Incomplete penetration
6. Weld features such as the geometry of the weld bead
7. Surface finish, due, for example, to oxide film or scales on the weld surface, weld slag or spatter.

#### 3.35.4.3.1 Weldment design

Weld joint design is a relevant factor to be considered in the overall corrosion performance assessment of equipment, and the design stage provides the best

**Figure 4** Possible crevice sites.

opportunity to avoid future corrosion problems relating to both the weld material and the weld geometry. The specification of the ideal geometry in regard to corrosion resistance has sometimes to be sacrificed in favor of the necessity to attend to other relevant construction aspects, for example, component flexibility. When possible, the weld should be located in an easily accessible area that allows for easy inspection, for example by nondestructive testing or even by visual inspection, and avoids stress concentration.

Some of the more significant features of weldment geometry are those that might cause crevice corrosion problems. These can be eliminated at the equipment design stage by a proper weld design, for example, by the use of butt rather than overlap welds. Weld joint geometry may affect the corrosion performance of a welded structure by creating conditions leading to dead volumes that may lead to accumulation of debris or corrosion products. These causes exacerbate corrosion by:

1. Allowing the area to remain wet longer than the rest of the equipment.
2. Contributing to the accumulation of aggressive species beneath them.
3. Allowing differentiated access of oxygen to the surface.
4. Preventing adequate drainage of equipment during downtime periods, rendering the fluid stagnant, and increasing the localized corrosion rate.

Some weld joint geometries may also cause crevice corrosion. For example, an overlap or T weld is an inevitable crevice former. Also, the use of skip welding instead of continuous welding introduces crevices, as illustrated in [Figure 5](#). In principle, these problems can be avoided by the application of a sealing weld. However, sometimes the solution is

**Table 4** Weld defects

<i>Defect</i>	<i>Causes</i>	<i>Remedies</i>
Hot cracks	Large solidification range Segregation Stress	More crack-proof filler Less fusion
Under bead cracks	Hardenable parent plate Hydrogen Stress	Low hydrogen process Planned bead sequence Preheating
Microfissures	Hardenable deposit Hydrogen	Low hydrogen process Pre- and post-heating
Toe cracks	Stress High stress Notches Hardenable parent plate	Planned bead sequence Pre-heating Avoidance of notches
Hot tears	Segregation Stress	Less fusion Cleaner parent plate
Porosity	Gas absorption	Remove surface scale Remove surface moisture Cleaner gas shield

not so straightforward because this might introduce unacceptable constraints into the equipment that can cause cracking or even promote other corrosion phenomena, such as SCC.

#### **3.35.4.3.2 Weldment backing**

A common deficiency of weld joint geometry is faulty weld penetration through the complete thickness of the section to be joined. Incomplete or excess penetrations are the two most serious defects in root passes, both of which have an impact on corrosion performance. In some geometries and welding positions, the root pass liquid weld metal pool tends to fall toward the interior of the structure resulting in excessive penetration. This can cause flow disturbance, particularly in small diameter pipes. Furthermore, splatter can also form on the internal surface. Both defects can compromise the corrosion performance of the equipment, and welders often tend to produce incompletely penetrated welds, which produce crevices in which corrosion can occur by the accumulation of aggressive species. To avoid this, backing rings can be used. These accessories help control the weld pool on the root pass, which is essential to produce a

satisfactory weld, allowing an easier inner surface alignment and an acceptable internal root profile. Furthermore, backing rings can have a chilling effect on the weld metal and the HAZ, reducing the total heat input which often has a positive impact on the HAZ width and weldment microstructures resulting from the welding operation. A common backing material is copper, which has a high thermal conductivity. However, other backing materials are also used such as anodized aluminum, stainless steel, mild steel, or even nonmetallic materials like ceramics.

Although the use of backing materials is positive from the welding standpoint, a permanent backing material may reduce the corrosion resistance of the weld joint. It creates an internal obstruction that will disturb flows and may induce erosion–corrosion, a crevice that may lead to crevice corrosion and possible galvanic incompatibility that may promote galvanic corrosion if the material is not chosen correctly. To overcome the disadvantages associated with permanent backings, inserts have been developed, that are consumed in the root pass, assuring complete penetration and a smooth root pass.

#### 3.35.4.3.3 Welding procedure or technique

Apart from incomplete or excessive penetration, other incorrect or inadequate aspects of welding operations can have an impact on the weldment corrosion performance. A weld is always a metallurgically inhomogeneous area compared to the parent material. Often, depending on welding parameters or cooling rates, this may lead to the formation of second phases, precipitates, grain boundary segregation, or even grain growth, which has consequences for the mechanical and corrosion properties of the weldment. Thus, an inappropriate thermal cycle can lead to a severe reduction in fracture toughness due to martensite formation in the case of carbon or low alloy steels, sensitization in the case of stainless steels, an inappropriate proportion of phases as in the case of

**Figure 5** Skip welding and crevice corrosion versus continuous welding. Reproduced from Landrum, R. J. *Fundamentals of Designing for Corrosion Control*; NACE, 1989.

duplex stainless steels, or secondary phase formation/distribution in the case of aluminum alloys.

Weld metal surface roughness or finish, or even the geometrical transition of the weld cap to the parent material, can provide stress raisers and therefore crack initiators in conditions with the potential for SCC or corrosion fatigue. Also, weld slag or spatter can create the conditions for crevice corrosion. Insufficient shielding gas protection can produce excessive oxidation of the welded area resulting in the formation of films or even scales that reduce the localized corrosion resistance, particularly in the case of stainless steels. Note that welding is much more readily controlled in the fabrication shop than in the field, and field repair welding presents particular challenges in relation to the control of procedures and techniques.

#### 3.35.4.3.4 Residual stresses and stress concentration

A weld is a geometric discontinuity that may concentrate residual, service, or applied stresses. Thermal contraction in the cooling stage and phase transition resulting from the welding process may introduce residual stresses in or at the vicinity of the weld joint, as shown schematically in [Figure 6](#). Furthermore, surface irregularities associated with the roughness of the weld bead or other defects may act as stress raisers. The resulting applied stress, that is, the sum of all stresses in a component, may introduce a vulnerability to phenomena such as corrosion fatigue, SCC, hydrogen induced cracking, or hydrogen embrittlement. The crack orientations will vary with the relevant stress fields:

1. Longitudinal cracks oriented parallel to the weld cord arise as consequence of transverse contraction.
2. Longitudinal cracks located on the middle of the weld cord arise as a consequence of an abnormal

**Figure 6** Schematic diagram of typical stress distribution across a butt weld.

stress level on the weld cord resulting from an improper welding technique.

3. Cracks on the weld edges result from the contraction stresses amplified by an edge effect.
4. Cracks on the HAZ parallel to the weld arise as a consequence of transverse contraction.

#### **3.35.4.3.5 Postweld heat treatment**

Sometimes, welding procedures require a postweld heat treatment (PWHT). This may be required by the construction code and may have an impact on the corrosion behavior of the weld area. PWHT is undertaken for a number of reasons depending on the requirements of the joint:

1. Annealing to produce recrystallization and eventually grain growth.
2. Softening to reducing the weld hardness in the HAZ.
3. Precipitation hardening to increase the strength
4. Stress relieving to reduce residual fabrication stresses.

These heat treatments may have an impact on the corrosion performance of the weld area to the extent that they might change the microstructure of the weld metal and HAZs, as well as the material surface condition, namely in regard to oxide formation. If a heat treatment is required and it is not adequately performed, it can induce detrimental changes, such as the sensitization of stainless steels or secondary phase precipitation that will strongly affect the corrosion performance of the weld. One of the most common examples of softening relates to materials intended for sour service in the oil and gas industry where materials are submitted to environments in which sulfide stress corrosion cracking (SSCC) may occur.

#### **3.35.4.3.6 Filler metal composition**

The weld metal composition is important from the corrosion standpoint. If the weld metal has a lower potential than the materials to be joined, it will corrode preferentially. Furthermore, due to its lower surface area, the corrosion current density for the corrosion process will be very high. In the case of autogenous welds, in which there is no separate filler material, the composition of the weld, *albeit* not necessarily the microstructure, is determined by the adjacent parent material. However, if a filler material is used, it should ideally be more noble than the material, or materials to be joined. Furthermore, when possible, the weld root should face the most aggressive fluid, because it will expose a smaller area.

### **3.35.5 Welding of Specific Materials**

#### **3.35.5.1 Introduction**

A review of the extensive work that has been undertaken since the previous edition on the corrosion performances of weldments in specific materials is beyond the scope of this chapter and the reader is referred to other sources such as *The Corrosion of Weldments*, edited by J. R. Davis, published by ASM International and the publications of relevant alloy suppliers. The pointers to weldment performance that are provided in the following sections are based mostly upon the material published in the previous edition with only minor updating.

#### **3.35.5.2 Carbon and Low-Alloy Steels**

Carbon steels undergo metallurgical transformations across the weld and HAZ, and a wide range of microstructures can be developed depending on cooling rates that in turn depend on factors, such as energy input, preheat, metal thickness, weld bead size, etc. Some typical microstructures for a carbon steel weld are shown in [Figure 7](#). Clearly, weld metal microstructures will be very different from those of the HAZ and parent material. Preferential corrosion of the HAZ is a common feature in a wide range of aqueous environments. Hardness levels will tend to be lower for high heat input processes such as submerged-arc welding than lower energy processes such as shielded metal arc.

The subject of weldment corrosion in offshore engineering was reviewed by Turnbull.<sup>23</sup> Galvanic effects are possible if the steel weld metal is anodic to the surrounding parent plate and is enhanced by the high anode to cathode surface area ratio that exists. Lundin<sup>24</sup> showed, for carbon steel, that weld metal deposited using a basic flux was less noble; acid fluxes resulted in a more noble weld metal, while rutile-based fluxes were intermediate. The nature of the surface and its prior treatment (e.g., peening) seemed to have no effect. It was also noted that the HAZ was no less corrosion resistant than the unaffected plate. Millscale and other heat oxides should always be removed by grit blasting as its presence can cause serious corrosion problems around welded joints. On the other hand, Saarinen and Onnela<sup>25</sup> considered that weld metal corrosion can be eliminated by using a suitably balanced electrode type, the remaining problem then being in the HAZ whose tendency to corrode (i.e., become more active) increased with increasing Mn content. Thus, the heat input during welding must be

**Figure 7** Variation of weld structure with distance from the welding seam center. Reproduced from ISQ training material.

important since a significant factor will be the cooling rate of the HAZ after welding. These findings have been substantiated by Ousyannikov *et al.*<sup>26</sup> using a scanning reference electrode probe. Increasing the heat input changed the weld metal from anodic to cathodic relative to the parent plate, although the presence of Ni reduced the magnitude of the effect.

The problem of grooving corrosion in line-pipe steel welded by high frequency induction or electric resistance welding has been studied. In sea water, it seems to be related to high sulfur content in the weld zone, the type of environment, its temperature, and velocity.<sup>27</sup> The importance of sulfur is significant since Drodten and Herbsleb have reported that localized corrosion at welded joints is more a function of S, Si, microstructure, and nonmetallic inclusion type and shape than of the local oxygen concentration.<sup>28</sup>

One of the major concerns in offshore construction is that of the corrosion fatigue. Turnbull<sup>24</sup> discusses this at length. Cracks usually originate at weld toes, the point of initiation being associated with crack-like defects (slag, nonmetallics, cold laps, undercuts, hot tears). These can constitute sharp notches situated at a point of maximum stress concentration due to the weld geometry. It is to be noted that although cracks initiate in the HAZ at the weld toe, the majority of crack propagation occurs in what is essentially unaffected parent plate. In air, it is possible to have cracks that grow at a decelerating rate until no further growth occurs, this is the 'short crack' problem widely discussed by Miller,<sup>29</sup> and the cracks are referred to as

nonpropagating cracks. On the other hand, similar cracks may continue to grow at an accelerating rate in a corrosive environment even though the stress may be below the fatigue limit. Burns and Vosikovsky<sup>30</sup> have given considerable attention to corrosion fatigue of tubular joints in structural and line-pipe steels. Crack initiation at the toe occurs after a small fraction of life, and long surface cracks can exist for over 50% of the life. On the other hand, laboratory tests on plate-to-plate welded specimens of the cruciform type show cracks which are much smaller for a larger percentage of the life, but their growth rate accelerates as the depth increases.

In sea water, the effects of cyclic frequency, stress ratio, electrochemical potential, oxygen content, and intermittent immersion at 5–12 °C have all been evaluated.<sup>31</sup> There is some evidence that at lower temperatures, seawater is less detrimental to fatigue life, but at all temperatures studied, the crack growth rate was always faster than in air. At intermediate ranges of stress intensity range ( $\Delta K$ ), there was a significant reduction in crack growth rate as the seawater temperature was reduced from 25 °C to 0 °C. Whilst the cracks are small and  $\Delta K$  low, calcareous blocking is very effective, and under these conditions and correctly applied cathodic protection (CP) consequently reduces the crack growth rate. As the crack length increases, blocking becomes less effective and the increased hydrogen embrittlement can accelerate the growth rate to values greater than experienced for the unprotected joints. Similarly,

Nibbering *et al.*<sup>31</sup> obtained data showing that CP raises the initial fatigue crack resistance but has little effect at a later stage of crack propagation. Even so, they considered that CP is still the most effective method for prolonging structural life under corrosion fatigue conditions. This is not unreasonable since crack initiation and early growth can represent a large proportion of the total life.

Marine fouling leading to the local production of H<sub>2</sub>S increases crack growth rate, but what the effect is when combined with CP is uncertain. Some of the factors mentioned earlier in connection with other steel corrosion problems are important to sulfide stress-corrosion cracking (SSCC). For example, the use of high strength low alloy steels in which carbon is reduced to below 0.05% combined with reduced sulfide segregation are beneficial to preventing SSCC of weldments.<sup>32,33</sup> SSCC of weld repairs in well-head alloys was investigated by Watkins and Rosenberg<sup>34</sup> who found that the repairs were susceptible to this problem because of the hard HAZs developed by welding. Postweld heat treatment was an essential but not complete cure compared with unrepaired castings. In the case of hydrogen-assisted cracking of welded structural steels, composition is more important than mechanical properties and the carbon equivalent should be <0.5%.<sup>35,36</sup> McMinn has presented much useful data concerning the fatigue crack growth rate in simulated HAZs of A533-B steels,<sup>37</sup> whilst Ray *et al.* have demonstrated the role of pitting corrosion of mild steel on crack initiation.<sup>38</sup>

### 3.35.5.3 Stainless Steels

There are four groups of stainless steels, each possessing their own characteristic welding problems:

1. Ferritic: Welding tends to result in a large grain size throughout the weld zone causing significant reduction in ductility. Also, the ferritic microstructure is susceptible to hydrogen embrittlement.
2. Martensitic: HAZ cracking is likely and may be remedied by employing the normal measures required for the control of hydrogen-induced cracking.
3. Austenitic: These steels may be readily welded but are susceptible to hot cracking, which may be controlled by permitting a small amount of residual delta ferrite in the weld.
4. Duplex: Welding of duplex alloys requires correct choice of weld material and procedures, in particular weld heat input, in order to ensure the retention of a satisfactory weld microstructure.

The corrosion of stainless steel welds was reviewed in the 1970s by Pinnow and Moskowitz<sup>39</sup> and, although this article is clearly dated in detail, the main general issues are still of relevance. Thus, main problems that might be encountered are weld decay, knife-line attack, and SCC, as illustrated in **Figure 8**.

#### 3.35.5.3.1 Ferritic and martensitic stainless steels

The more traditional compositions with a relatively high (C + N): Cr ratio carry a risk of martensite formation in the HAZ during cooling.

Furthermore, there is a risk for carbide precipitation and therefore, for intergranular corrosion. More modern grades of ferritic stainless steel have a low (C + N): Cr ratio and possess stabilizing elements added to the material to reduce the likelihood of intergranular corrosion. Ferritic stainless steels are also liable to grain growth in the HAZ, as illustrated in **Figure 9**. Therefore, heat input should be kept to a minimum, **Figure 9**. Also, insufficient gas protection during welding may lead to chromium nitride formation due to N<sub>2</sub> uptake from the atmosphere, and consequently, to embrittlement and decreased corrosion resistance. Finally, the gas used for shielding as well as the metal surface should be free of H<sub>2</sub> sources (e.g., moisture, oil, and grease) in order to avoid hydrogen embrittlement.

#### 3.35.5.3.2 Austenitic stainless steels

Although readily welded, these are susceptible to hot cracking which may be overcome by balancing the weld metal composition to allow the formation of a small amount of  $\delta$ -Fe (ferrite) in the deposit, optimum crack resistance being achieved with a  $\delta$ -ferrite content of 5–10%, as illustrated in **Figure 10**. More than this

**Figure 8** Common sites of corrosion in stainless steel welds; typical peak temperatures attained during welding (°C) are given at the foot of the diagram. Note that knife-line attack has the appearance of a sharply defined line adjacent to the fusion zone.

**Figure 9** Ferritic stainless steel weld showing large grain size in the weld and heat affected zone.

**Figure 10** Dendritic ferrite in an austenite weld (left); heat affected zone (center); equiaxed austenitic grains in the parent metal (right).

concentration increases the possibility of  $\sigma$ -phase formation if the weldment is used at elevated temperature consequently reducing both mechanical and corrosion properties. Any adverse effects of the  $\delta$ -ferrite on corrosion resistance are usually overcome by slight enrichment of the filler metal composition relative to the parent material. However, in certain critical applications such as the manufacture of urea,  $\delta$ -ferrite can reduce corrosion resistance to an unacceptable extent in which case fully austenitic welds are required.

Prasad Rao and Prasanna Kumar<sup>40</sup> undertook electrochemical studies of austenitic stainless steel claddings to find that heat input and delta ferrite content significantly affected the anodic polarization behavior under active corrosion conditions, whilst Herbsleb and Stoffelo found that two-phased weld claddings of the

24Cr–13Ni type were susceptible to intergranular attack (IGA) as a result of sensitization after heat treatment at 600 °C.<sup>41</sup>

### 3.35.5.3.3 Duplex stainless steels

These steels have a better weldability than ferritic steels. They are purely ferritic at high temperatures, and if quenched rapidly they may remain predominantly ferritic and the ferrite phase is sensitive to chromium nitride and brittle phase formation. Modern duplex stainless steels have a high content of nitrogen, which is an austenite stabilizer. This facilitates austenite formation at high temperatures and consumes the nitrogen, preventing the formation of nitrides in the ferritic phase. Duplex filler metal is also formulated with more nickel than the parent

material to promote austenite formation. As a result, the as-welded structure has a balance of ferrite and austenite that is close to the equilibrium structure of the parent material. Nitrogen additions to the weld shielding gases also assist in maintaining the correct composition of the weld and heat affected zones. Duplex stainless steels are also susceptible to intermetallic phase formation approximately in proportion to their chromium and molybdenum contents. This decreases the corrosion resistance and mechanical properties such as toughness. Precipitation of intermetallic phases is favored by high heat inputs that need to be controlled, particularly in thick sections, to avoid adverse effects.

#### 3.35.5.3.4 Sensitization

Carbide precipitation and growth causes the formation of a chromium depleted area around the grain boundaries and chromium carbide formation at the grain boundaries. When sensitized material is subjected to an aggressive medium, preferential attack occurs.

Sensitization results from exposure of the material to high temperatures, either during production, or as a result of welding operations. Sensitization temperatures are in the range 425–815 °C. Although sensitization is primarily caused by chromium and carbon, other elements present in the stainless steel may play a secondary role in sensitization. Thus, Ni increases carbon activity in the solid matrix; favoring carbide precipitation and Mo has behavior similar to chromium, although it is usually present in lower amounts.

Nowadays, most commercial grades of stainless steel are of an 'L' grade and low in carbon. Hence, sensitization rarely occurs; as can be seen in [Figure 11](#), reduction in carbon concentration greatly increases the time required for sensitization to occur. However, surface sensitization, most commonly from surface hydrocarbon contamination (i.e., from oil and grease) remains an issue. Sensitization can only be reversed by heat-treatment to affect a re-solution of the chromium carbide (preferably at ~1050 °C), which is generally impractical in most structures.

Under certain conditions, it is possible for a weldment to suffer corrosive attack which has the form of a fusion line crack emanating from the toe of the weld; this is termed knife-line attack. It is occasionally experienced in welded stainless steels that have been stabilized against sensitization by addition of titanium, niobium, or tantalum. The niobium-stabilized steels are more resistant than the titanium-stabilized types by virtue of the higher solution temperature of NbC, but the risk may be minimized by limiting the carbon

**Figure 11** Time-temperature diagram for IGA of 18Cr 9Ni stainless steels with different carbon contents in sulfuric acid-copper sulfate tests showing that lower carbon contents increase the time required for sensitization. Reproduced from *Corrosion Handbook, Stainless Steels*; AB Sandvik Steel, 1994.

content of the steel. Knife-line attack is described in detail in [Chapter 2.24, Corrosion in Nitric Acid](#).

#### 3.35.5.3.5 Localized corrosion at weldments

The various forms of SCC are described in separate chapters in this book. SCC is particularly dangerous because of the insidious nature of the phenomenon. The residual stresses arising from welding are often sufficiently high to provide the necessary stress condition, whilst a chloride-containing environment in contact with the austenitic stainless steels induces the typically transgranular and branched cracking. Increased nickel content marginally improves the resistance of the steel to this type of attack. Also, the ferritic steels and duplex steels with at least 50% ferrite have high resistance to chloride-induced transgranular SCC.

IGA, pitting, and crevice corrosion are problems commonly associated with the stainless steels and their welds. For example in the duplex stainless steels, the corrosion resistance, particularly in terms of pitting and crevice corrosion, depends on microstructure, that is, the relative proportions of ferrite and austenite, the lattice concentration of dissolved nitrogen, and the segregation of alloying elements between the ferrite and austenite phases.<sup>42–44</sup> These may be affected by heat input and welding procedures.<sup>45</sup> Grekula *et al.*,<sup>46</sup> studying pitting corrosion of gas tungsten arc welds in austenitic steels, found that the final interdendritic regions to solidify in primary austenite welds and the austenite interfaces in primary  $\delta$ -ferrite welds are the most susceptible sites for pit initiation. Sulfur also affects pitting

potential and increases the pit density but has no effect on the pit growth rate.<sup>47</sup> Also, pitting in or adjacent to tungsten inert gas (TIG) weld beads in tap-water may be caused by the surface oxides formed during welding and is generally due to inadequate root gas shielding.<sup>48</sup> It is essential, for optimum resistance to localized corrosion initiation, to remove any weld tint using appropriate pickling fluids/pastes such as nitric acid or light blasting with, for example, rounded glass beads.

Controlled additions of nitrogen have been made to 439 steel weld metal to prevent IGA,<sup>49</sup> whilst additions of Y or Ce to an 18Cr–12Ni steel have also been found to be beneficial.<sup>50</sup> In the case of TIG-welded Mo-containing stainless steels,  $\sigma$ -phase formation can be responsible for IGA in hot oxidizing (e.g., nitric) acids.<sup>51</sup>

#### 3.35.5.4 Nickel Alloys

In the main, welding does not seriously affect the corrosion resistance of the high nickel alloys, and the resistance to stress corrosion is particularly high. Earlier versions of the N–Cr–Mo and Ni–Mo families of alloys had limited thermal stability and were vulnerable to the precipitation of deleterious intermetallic phases during welding. Thus, in the case of the Ni–Cr–Mo–Fe–W type alloys, Samans<sup>52</sup> suggested that the material should be given a two-stage heat treatment prior to single-pass welding in order to produce a dependable microstructure with a thermally stabilized precipitate. In the case of the Ni–28Mo alloy, it was suggested that a special case of selective corrosion analogous to the weld-decay type of attack could be removed by solution treatment or using an alloy containing 2% V.<sup>53</sup> The more recent grades of these alloys have been alloyed to provide much greater thermal stability and are much less vulnerable to loss of corrosion resistance during welding. The chromium-containing alloys can be susceptible to weld decay and should be thermally stabilized with titanium or niobium, and where conditions demand exposure to corrosive media at high temperatures a further post-weld heat treatment may be desirable.

Of the weldability problems, nickel and nickel-based alloys are particularly prone to solidification porosity, especially if nitrogen is present in the arc atmosphere, but this may be controlled by ensuring the presence of titanium as a denitrider in the filler and maintaining a short arc length. The other problem that may be encountered is hot cracking, particularly in alloys containing Cr, Si, Ti, Al, B, Zr, S, Pb, and P. For optimum corrosion resistance, it is recommended that

similar composition fillers be used wherever possible, although overmatching with, for example, molybdenum can compensate for any elemental segregation inherent in the weld metal. Obviously any flux residues that may be present must be removed.

#### 3.35.5.5 Aluminum Alloys

These alloys are susceptible to hot solidification cracking and in order to overcome this problem some aluminum alloys have to be welded with a compensating filler of different composition from that of the parent alloy; this difference in composition may lead to galvanic corrosion. A further problem in the welding of these materials is the high solubility of the molten weld metal for gaseous hydrogen which causes extensive porosity in the seam on solidification; the only effective remedy is to minimize hydrogen pick-up by using a hydrogen-free gas shield with dry, clean consumables (e.g., welding rods, wire), and parent plate.

In general, however, the corrosion resistance of many aluminum alloys is not significantly reduced by welding. Any adverse effects that may be encountered with the higher strength alloys can be largely corrected by postweld heat treatment; this is particularly true of the copper-bearing alloys. Pure aluminum fillers impart the best corrosion resistance, although the stronger Al–Mg and Al–Mg–Si fillers are normally suitable; the copper-bearing fillers are not particularly suitable for use in a corrosive environment.

The HAZ may become susceptible to SCC, particularly in the high-strength precipitation hardened alloys. In this context for Al–Zn–Mg type alloys, it has been shown that maximum sensitivity appears to occur when there is a well-developed precipitation at the HAZ grain boundaries adjacent to the fusion line, a fine precipitate within the grain and a precipitate-free zone immediately adjacent to the grain boundaries.<sup>54</sup>

#### 3.35.6 Protection of Welded Joints

Structural steels are frequently protected from corrosion by means of a paint primer, but these materials can have an adverse effect on the subsequent welding behavior, and this is mainly observed as porosity.<sup>20</sup> Hot-dip galvanizing for long-term protection can also lead to porosity and intergranular cracking after welding, in which case it may be necessary to remove the zinc coating from the edges of the parent material prior to welding. The presence of zinc can also lead to operator problems due to the toxicity of the fume

evolved unless adequate fume extraction is employed. After welding and prior to painting, all welding residues must be removed and the surface prepared by grinding, grit blasting, wire brushing, or chemical treatment. This preparation is of fundamental importance, the method of applying the paint and the smoothness of the bead apparently having little effect on the final result.<sup>55</sup>

In the electric-resistance welding of hot-dipped galvanized steel, welding had little effect on the seawater corrosion of the coated steel when compared with the uncoated steel, the latter showing considerable corrosion after 12 months exposure.<sup>56</sup> The subject of galvanizing and the welding of structural steels has been given special attention by Porter,<sup>57</sup> but by far the most common method of protection is by painting which McKelvie<sup>58</sup> discusses in terms of fundamentals of paint as a corrosion barrier and the cleaning and coating procedures necessary to achieve protection of welded structures. In these articles, he covers the type of contaminants arising from welding as well as cleaning methods, blast primers, galvanizing, coating removal for repair welding, wire brushing, and chemical treatments. Lloyds Register of Shipping lists the proprietary products that have no significant deleterious effects on subsequent welding work.<sup>59</sup>

### 3.36.1 Introduction

It may seem rather at odds with the general scope of Shreir's Corrosion to include a section on adhesives as these materials are not normally employed as a mechanism of combating corrosion, or recognized as being susceptible to it, although they will, and do undergo environmental degradation. The justification is, however, very straightforward; adhesives are now widely used to bond metal components; metal components corrode, and such corrosion processes may compromise the performance of an adhesive joint, either at the bonded interface or adjacent to it. This chapter seeks to bring together the current state of knowledge regarding failure mechanisms in adhesive joints (much of it obtained from studies of the behavior of organic coatings applied to effect corrosion protection of a metallic substrate) and provide guidelines as to how various failure types may be identified.

Adhesive bonding has reached a level in manufacturing industry where the process can truly be said to be ubiquitous. Applications range from the rapid robotic assembly of small components to the structural adhesive bonding of massive parts in the aerospace and civil engineering industries. Against this background, there is a need to understand failure mechanisms that

may occur in adhesively bonded structures during their lifetime and design out such weaknesses. In terms of the initial load-bearing capacity, and subsequent lifetime under well defined conditions, of an adhesive joint, this can be readily determined from standard monotonic or fatigue tests. Arguably, however, the most important attribute of an adhesive joint is the durability that it possesses, that is the level of the original joint strength that will be retained over the lifetime of the structure. The life expectation of an adhesive joint can vary from a few days or weeks for foodstuffs packaging to more than 25 years for an aircraft! Thus, the focus of much adhesive bonding research over the last three decades has sought to catalogue and understand the issues associated with the durability of adhesive joints. The term durability in its strictest sense refers to the exposure of an adhesive joint or adhesively bonded structure to any aggressive liquid (or vapor) phase and as such includes reagents as diverse as fuel, deicing liquid and brake fluid! The generally accepted definition, however, of joint durability refers to the environmental exposure to water. The reason for this is that although durability is the performance of an adhesive bond in any chosen environment, the most aggressive environment as far as the metallic substrate–adhesive interface is concerned is water, and the term durability,

when applied to adhesives, has become synonymous with bond performance when exposed to water in its vapor or liquid form.

In seeking to understand the role of water on the degradation of joint durability, one must be aware that there are several distinct processes that can take place, leading to failure, resulting from different diffusion paths for water molecules in the adhesive and the presence, or otherwise, of electrochemical activity at the coated metallic surface. This gives rise to three distinct failure processes; interfacial failure as a result of hydrodynamic displacement of the adhesive from the substrate, the degradation of the adhesive itself in the environs of the substrate–adhesive (known in the adhesives community as plasticization), and the interfacial failure as a result of cathodic or anodic activity at the substrate, referred to as either cathodic delamination or anodic undermining. The mechanistic aspects of these three processes are well understood and can be related to exposure parameters.

The kinetics of failure is a function of both the environment and design parameters. In some situations, there may be more than one mechanism in operation, and the one that proceeds fastest will invariably become the rate-controlling step, but although it may prove possible to stifle such a mechanism, failure may still occur, albeit at a slower pace, as a result of the kinetics associated with the minor process. A number of authors have attempted to relate experimental observables to a unified mechanism that may serve as a design guide. Test geometries employed have varied from very simple tension or peel geometries to more sophisticated fatigue test pieces. Similarly, some authors have set out to investigate a particular failure process, such as cathodic delamination, while others have set out to study joint performance and have related durability to corrosion processes in an effort to gain a complete understanding of how failure has occurred. This chapter reviews mechanisms of failure, considers the various rate models that have been derived on the basis of empirical results, and finally, suggest ways in which adhesive joint design and specification can be used to reduce the detrimental effects of corrosion on joint durability.

### 3.36.2 Mechanisms of Failure

#### 3.36.2.1 Hydrodynamic Displacement

The interfacial thermodynamics associated with an adhesive joint are readily addressed using the concepts of interfacial free energy of the substrate,

adhesive, and water. Following is the well known Young–Dupré, which defines the thermodynamic work of adhesion ( $W_A$ ) as

$$W_A = \gamma_S + \gamma_A - \gamma_{AS} \quad [1]$$

where  $\gamma_S$  is the surface free energy of the (oxidized) metal substrate,  $\gamma_A$  is the surface free energy of the adhesive (normally a figure for a generic type of adhesive, such as epoxies, will be used), and  $\gamma_{AS}$  is the interface free energy associated with the substrate–adhesive junction. In a dry environment, the  $W_A$  parameter will assume a positive value indicating that the joint is thermodynamically stable. Something that is self evident by visual inspection and mechanical testing will invariably yield a failure within the adhesive layer, often at about the midpoint of the glue line thickness. The important feature here is that from both a thermodynamic standpoint and by experiment, when tested in a dry environment, the interface between substrate and adhesive is strong and stable. The exception to this observation is if a contaminant layer is present on the substrate, such an occurrence will compromise joint strength and lead to an interfacial failure. For this reason, such contamination, known as a weak boundary layer, is to be avoided at all costs in adhesive bond fabrication.

Although stable in a dry atmosphere, the exposure of such a joint to a humid or wet environment can lead to the diffusion of water along the interface, from the exposed joint edge, as indicated in [Figure 1](#). Following the approach of Gledhill and Kinloch,<sup>1</sup> [eqn \[2\]](#) can be written to predict the work of adhesion  $W_A^*$  in the presence of a third liquid phase, considering the three interfaces that are now involved:

$$W_A^* = \gamma_{SL} + \gamma_{AL} - \gamma_{AS} \quad [2]$$

where the addition of subscript L indicates the interface free energy of substrate or adhesive in contact with the liquid, as indicated in [Figure 1](#). Gledhill and Kinloch were able to show that when the values of

**Figure 1** The spontaneous displacement of an adhesive layer on an oxidized metal substrate (e.g., aluminum); the quantity  $W_A^*$  will be negative as predicted by [eqn \[2\]](#).

$W_A^*$  were negative (indicating that the process is thermodynamically favorable), there was a good correlation with empirical results in which a variety of joints were exposed to various liquids. Calculated values of  $W_A^*$  from these systems were either positive or negative, and those with a negative value showed spontaneous (but not instantaneous) separation when exposed to the liquid. (The term spontaneous is used in the thermodynamic sense, meaning energetically favorable, and has no implications regarding the kinetics of the process. This usage should not be confused with the same word taken in a sense to mean instantaneous, as in the term spontaneous combustion much favored by the popular press!)

Although outside the scope of this article, it must be appreciated that such an approach is only valid when the forces of adhesion are a result of van der Waals forces, more usually subdivided into dispersion and polar forces. These forces are generally rather weak and readily compromised by the presence of water. Specific interaction at interfaces, such as covalent bonds or donor–acceptor interactions (also known as acid–base bonds, of which hydrogen bonds are an important subcategory), are not so susceptible to degradation by water, and for this reason, the energetics approach described above is not applicable, and the presence of such bonds at the substrate–adhesive interface has, in itself, the propensity to improve bond durability.

Thermodynamic considerations indicate a true interfacial failure, as described above, and this can be established by the use of surface analysis methods such as X-ray photoelectron spectroscopy (XPS) and time-of-flight secondary ion mass spectrometry (ToF-SIMS). As some failure mechanisms may leave vanishingly thin adhesive residues on the substrate (<5 nm), the use of optical or scanning microscopy, analysis by EDX or FT-IRS is really not good enough, and methods that can explicitly provide a chemical analysis of such very thin layers are required.

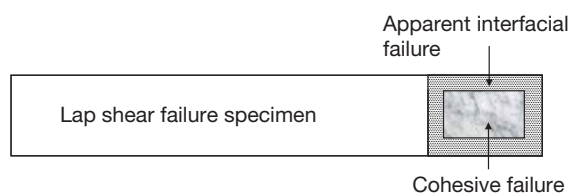

Although the study of organic coatings provides valuable mechanistic information regarding failure modes that can be transferred directly to studies of the failure of adhesive joints, there is one major difference that must be considered when making this analogy. In the case of coatings, downward diffusion of water molecules, perhaps mitigated by the concomitant diffusion of solvated ions, is always likely to occur, whereas in the case of adhesively bonded substrates, this is only an important consideration if one or other substrate is permeable to water. This is clearly not the case in the adhesive bonding of

metallic substrates, although it may become so if one or other of the substrates is a polymeric material, or if so-called ‘open-face’ model joints are being considered. Thus, the usual pathway for the diffusion of water and other aggressive or deleterious species is laterally from the joint edge, either along the interface, as considered in Figure 1, or within the adhesive layer itself. This route gives rise to a characteristic failure that moves inwards from the edge of the joint, giving rise to the characteristic picture-frame morphology as illustrated in Figure 2. This failure appearance may be a result of thermodynamic displacement or any of the other failure mechanisms discussed in the following section.

In summary, the presence of water at the interface of an adhesive joint generally leads to instability at the interface, resulting in interfacial failure, readily identified by XPS and ToF-SIMS. Simple thermodynamic calculations enable joint stability to be predicted from the knowledge of surface and interface free energies. It must be noted, however, that it provides no indication of the kinetics of failure, which must be established by empirical studies.

### 3.36.2.2 Adhesive Plasticization

All polymeric adhesives are permeable to water, and although water molecules can only enter through the edge of the joint, there is then the possibility that they can diffuse throughout the glue-line thickness. This can give rise to a degradation of the mechanical properties of the adhesive that is usually known by the catch-all term of plasticization. Water molecules can aggregate close to the interface with the substrate, which leads to swelling of the polymer and the subsequent reduction in durability. This process is analogous to the wet adhesion phenomenon observed in paints and shows the same behavior, in that, it is reversible to a large extent. Heating, or simply leaving joints that have been exposed to

**Figure 2** Picture frame failure, the typical appearance of a joint, which has been exposed to water, leading to an apparent interfacial failure from the edge inwards (the picture frame) and a central cohesive region (the picture), which has not been affected by water and provides the joint with residual strength.

water in relatively dry air is able to remove the water, and values approaching the original dry strength can easily be achieved.<sup>2,3</sup> The diagnostic of this type of failure is once again made by a careful examination of the substrate failure surface. Unless there is ready route to the interface from the bulk of the adhesive for the water molecules, they will not aggregate at the interface but only very close to it. Once again, surface analysis has an important role to play in the forensic analysis of failures in order to define the locus of failure at the molecular level. **Figure 3** indicates, schematically, the concepts of interfacial and cohesive failure, and the thinner the layer of adhesive remaining on the substrate in the cohesive example, the more challenging the analysis. The role of surface analysis in adhesion studies has recently been reviewed,<sup>4</sup> and examples of different failure types, as deduced from the application of such methods, will be presented at the end of this section.

### 3.36.2.3 Corrosion Induced Failure

#### 3.36.2.3.1 Cathodic failure

The occurrence of corrosion at the exposed substrate of an adhesive joint leads to a localized corrosion phenomenon, in that the anodic and cathodic sites are separated with the exposed metal undergoing anodic oxidation, and the electrons produced are

consumed at a cathodic site at the adhesive–substrate interface, where hydroxide ions are produced by the reduction of water and oxygen molecules. The reactions involved are the standard ones and are given below for an iron substrate.

At the exposed metal, the anodic reaction occurs

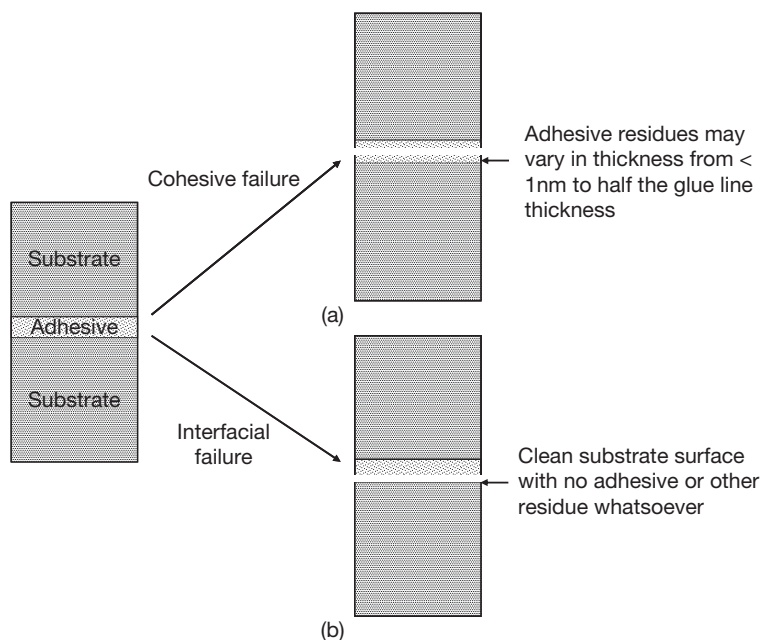

While at the cathode, two reactions are possible depending on the electrode potential, the more usual one being

Although at potentials more noble than 1020 mV (versus the saturated calomel electrode), water reduction, leading to the evolution of hydrogen, is dominant:

Reaction [5] occurs at a potential below that, which develops at the free corrosion potential of iron, and is generally considered to be important only when metal substrates are deliberately polarized cathodically, such as in impressed current cathodic protection schemes or laboratory based simulations of the same. Both cathodic reactions lead to the generation of hydroxide ions, which creates an alkaline environment in and around the adhesive–substrate interface.

**Figure 3** Schematic representation of (a) cohesive and (b) interfacial loci of failure.

The deleterious effect of such an alkaline environment on polymer to metal adhesion was first reported by Evans in 1929<sup>5</sup> in a paper entitled ‘The Electrochemical Corrosion of Painted Steel with Special Reference to the *Alkaline Peeling* of the Coat.’ This phenomenon received scant attention until the 1970s when the term cathodic disbondment (or variously disbonding or delamination) was coined to describe the separation of a polymer from the cathodic region of a coated metal. At the time, the examples of cathodic delamination that were cited included the adhesion loss of a paint film adjacent to a stone chip on an automobile or the failure of powder coatings on cathodically protected gas and oil transmission line pipe. Interestingly, both these examples had important technological consequences and led to an upsurge in research activity in the process of the mechanisms of cathodic delamination, most notably by groups led by Leidhesier, using electrochemical methods<sup>6,7</sup> and Dickie (at Ford USA)<sup>8,9</sup> and Castle (at the University of Surrey UK),<sup>10,11</sup> using XPS. The various mechanisms implicated in the cathodic delamination process were reviewed in the following decade by Leidhesier<sup>12</sup> and Watts.<sup>13</sup> Castle attempted to shed fresh light on the process in 1996, with a critical assessment of the role of water within the polymer in the failure process.<sup>14</sup>

The basic premise of cathodic delamination is very straightforward in that oxygen and water arrives at the cathodically polarized metal surface and, following eqn [4], hydroxide ions are produced, leading to an increase in the pH in the environs of the polymer–metal interface. This underfilm alkalinity attacks the interfacial bonding directly, in the manner proposed by Evans,<sup>5</sup> leading to adhesion loss. In practice, such a failure is observed visually on low carbon steel as the rather unusual and counter intuitive observation in that the organic coating readily peels from the steel, but the steel has a very clean, unruined, appearance. The classic situation of a localized defect in an organic coating on steel is indicated in Figure 4. In this situation, the exposed metal undergoes anodic dissolution, the electrons produced are consumed in the annular cathodic zone surrounding the initial defect, water may arrive at the tip of the disbondment crevice by lateral diffusion from the defect or by downwards diffusion through the thickness of the coating, and the process which supplies the water molecules most quickly will be the one that is rate controlling. As the process continues, the anodic area will grow, consuming the delaminated cathodic area that will also extend, leading to increased coatings failure. This type of failure is

**Figure 4** The electrochemical reactions that occur at a defect in an organic coating exposed to an aqueous solution. The anodic reaction occurs at the defect and cathodic reduction of water is localized within an extending crevice beneath the coating.

readily observed on painted steel structures where macroscopic or microscopic defects in the coating have developed. The cathodic and anodic areas are visually quite easy to separate, but in some cases, there is a need to be absolutely certain about the mechanism of failure, and in such cases, a useful analytical solution is to make use of the observation that electrode surfaces will retain their electrochemical signature once removed from the electrolyte and analyzed by a surface analysis method such as XPS.<sup>15</sup> In essence, the surface alkalinity needs metal cations (often  $\text{Na}^+$ ) to balance the cathodically generated hydroxide ions, and as most electrolytes will have sufficient ionic species, the cathodic region can be identified by retained cations of this type. In a similar vein, anodic regions will retain marker anions such as  $\text{Cl}^-$ . Although the concentration of such ions is at monolayer coverage or less, it is a routine matter to determine their presence and concentration by XPS. Thus, in XPS, there is a useful methodology in which mechanism of failure can be confirmed, as will be shown in the next section.

The scenario of Figure 4 is clearly the situation that exists when a polymer–metal system, be it adhesive or coating, is at the rest potential (free corrosion potential) of the metallic substrate. Although this situation occurs quite often, there is another regime that can render the cathodic delamination process even more destructive, that is, when the metal substrate bearing the adhesive or coating is polarized cathodically. This can occur as a result of a deliberately applied potential (as is the situation with impressed current cathodic protection), but more often, it occurs when the metal is coupled to a more active metal. Much of the early work relating to cathodic delamination was carried out in this manner using either an ASTM Specification<sup>16</sup> in which coated steel was coupled to a zinc anode or a UK approach<sup>17</sup> in which the coated panel was polarized

cathodically to a potential of 1.5 V versus the saturated calomel electrode, as shown in **Figure 5**. This latter test was much favored by the coatings end-users who found that it was able to discriminate coating performance very rapidly at a fairly rudimentary level. Many in the business found that it was a very severe test, with oxide reduction occurring as a precursor to coatings failure, something which the Pourbaix diagram for iron predicts will only happen at the extremes of cathodic potential and pH! Notwithstanding these possible shortcomings, this test is widely used, and performance of high performance fusion bonded coatings is frequently quoted against such a test by coatings manufacturers.

The mechanisms for destruction of the polymer-metal interface and failure of coating or adhesive appear to be fairly similar, irrespective of the source and magnitude of the cathodic potential; however, the kinetics of failure vary quite considerably, and this in turn is a direct consequence of the flux of hydroxide ion produced during the cathodic reduction process. It is informative to consider the quantities involved using data published many years ago.<sup>11</sup> In the examination of the delamination of a powder sprayed epoxy coating from a cathodically polarized ( $-1.5$  V versus SCE) mild steel substrate, a delamination rate of  $0.4 \text{ mm day}^{-1}$  was established for a range of surface profiles once a correction for interfacial path length had been made. By converting the delamination rate to a more convenient unit, one arrives at a crack growth rate of  $5 \text{ nm s}^{-1}$ . From the knowledge of the rate at which a typical interface separates, the rate at which such an interface is exposed can be calculated, and then, by the application of Fick's law of diffusion, the flux of hydroxide ions required to

sustain these kinetics can be inferred. The results of such a modeling approach lead to a flux of  $10^{-15}$  mole of hydroxide ions per second, and the application of Fick's Law indicates a concentration gradient within a disbondment crevice of  $10^{-3} \text{ mole dm}^{-3} \text{ cm}^{-1}$ , that is, a pH of at least 11. Using a similar approach, the current density required to sustain a rate of  $5 \text{ nm s}^{-1}$  is estimated at  $6 \times 10^{-11} \text{ A cm}^{-2}$ . This is extremely low, and it is unlikely that this is the rate-controlling step in the disbondment process, and this leads one to the inescapable conclusion that diffusion of hydroxide ions along the metal-polymer interface is, indeed, the rate-controlling step, and when the required concentration gradient is maintained, the process will continue unabated.

### 3.36.2.3.2 Anodic failure

The two failures described above, hydrodynamic displacement of the organic phase, and the cathodic delamination of the coating or adhesive as a result of a local increase in pH, are routinely observed, whereas the failure of the polymer-metal interface as a result of localized anodic activity is unusual. In the coatings field, there are well documented examples of the anodic undermining of a lacquer on tin plate for foodstuffs<sup>18</sup> and the failure of an acrylic repair coat on an aluminum brass substrate,<sup>19</sup> but otherwise, examples are rare. In the examination of the failure mode of adhesively bonded hot dipped galvanized steel, Fitzpatrick and Watts<sup>20</sup> showed that failure was a result of localized microelectrodes occurring at the metal-adhesive interface, but it was in the regions of cathodic activity that interfacial failure occurred; the other failure regions, presumably in the region of the microanodes, were essentially cohesive in nature,

**Figure 5** Schematic representation of the cathodic disbondment test.

indicating that the electrochemical activity in the environs of the anodic sites was not as deleterious as the increase in pH experienced at the microcathodes.

### 3.36.3 Identification of Locus of Failure and Failure Classification
